LECTURES

INTRODUCTORY TO THE COURSE OF THE
INSTITUTES OF MEDICINE,

DELIVERED BY

ROBERT J. GRAVES, M.D.,

King's Professor, Dublin.

LECTURE VIII.

GENTLEMEN,—At our last meeting we discussed the nature of that innate tendency displayed by mankind to become affected by a common impulse, a tendency which we called the instinct of imitation, and which has often given rise to events the most important.

At the commencement of the Christian era a monomania of migration appears to have seized the nomade tribes residing in the north-eastern parts of Europe and the west of Asia, and gave rise to those successive inundations of warlike hordes, which, for the time, nearly extinguished civilisation in the countries they invaded, but proved finally the means of giving birth to those principles of civil and religious freedom that now prevail in European society. No nation has suffered more from the sudden working of this passion than the Jews, whose history in Germany, France, Spain, and England exhibits so many intervals of repose, interrupted by violent persecutions carried on by the frantic populace with all the symptoms of temporary insanity. When accident, or the wickedness of some malicious person, had succeeded in producing a persecution of the Jews in any one city, the effect of this example was often sufficient to arouse the dormant passions of the rest of Christendom, and the persecution speedily became general. Shortly after the successful voyages of Columbus, in search of the New World, all the maritime nations of Europe were seized with a mania of discovery, and the dreams of society were every where gilded with the wealth of unknown regions, with the treasures of Eldorado. This passion ruined thousands it is true, but the enthusiasm it generated enabled man to overcome difficulties to all appearance

insurmountable, and, in a comparatively short space of time, he was rewarded with a knowledge of geography, the enlightened parent of commerce. I need not remind you, gentlemen, of those periods of history when the votaries of astrology and alchemy successively forged chains, in which society was led away captive, neither is it necessary to advert to the lasting effects produced by the passing mania of knight-errantry; all these subjects have been treated of fully by authors of ability.

As communication improves by means of steam-vessels, rail-roads, and other contrivances, the brilliant results of the mechanical genius of the age, society will be placed in a situation still more liable to the influence of this instinct, a circumstance imperatively demanding the consideration of those whose duty it is to frame laws for the government of mankind. Formerly the inhabitants of any particular shire, or district, were almost insulated, and held little intercourse with the rest of their countrymen, and consequently very different feelings, customs, and opinions prevailed in the different parts of the same nation, and served together, with difference of dialect and accent, to prevent the origin of a common sympathy. Trifling as the circumstance may appear, there can be little doubt that the difference of costume, which was then observable in each county, served to render the line of demarcation still stronger. Society, thus subdivided into a great number of distinct parts, was not, except on extraordinary occasions, liable to be affected by one common impulse. This state of things no longer exists; the tendency of modern improvement has been to remove the impediments which separated one part of the population from another, its effects have fused all into one common mass; nations are now more closely connected, and maintain a more frequent, rapid, and perfect intercourse with each other than formerly existed between different subdivisions of the same kingdom. In consequence of this change, as yet by no means fully accomplished, man is fast approaching to a state, in which the heaving of the public mind, no longer confined by the limits of a district, or the boundaries of a nation, will spread with rapidity from people to people,

acquiring in its course force, magnitude, and buoyancy, and rolling onward an ocean wave from hemisphere to hemisphere. Raised by the storm of social agitation in the New World, already has it traversed the deep, and precipitated itself on France, has prostrated the most venerable institutions, the most stable monuments of the old; already, reflected back across the Atlantic, has it broken on the shores of South America, shaking, as it fell, the very foundations of that mighty Continent.

The workings of the instinct of imitation are extremely varied, and comprise all those different impressions which suddenly, and unaided by the exercise of the judgment, infect any numerous body of individuals. The panics that have so often arisen in the best disciplined armies must be thus accounted for. The well known "*saute qui peut*," which hastened the final catastrophe of the hard fought field of Waterloo, is not without a parallel in the annals of the British army. Napier, in his admirable history of the War in the Peninsula*, records a remarkable instance of a panic in that division of our army which, above all others, was distinguished for valour and discipline:—

"On the 22nd Sept. 1810, General Pack destroyed the bridges over the Criz, and fell back upon the light division, but on the 23rd the enemy re-established the communication, passed the river, and obliged the British horse to quit the plain and take to the hills behind Montago. Three squadrons of light and one of heavy cavalry were retained there by Lord Wellington, but the rest he sent over the Sierra de Busaco to the low country, about Milhadra, whence he recalled Spencer, and, at the same time, caused the third and fourth divisions to take their ground on the position of the former, at St. Antonio de Cantara, the latter at the convent; the light division, falling back only a league, then encamped in a wood, where happened one of those extraordinary panics that in ancient times were attributed to the influence of a hostile god. No enemy was near, no alarm was given, yet suddenly the troops, as if seized with a frenzy, were startled from sleep and dispersed in every direction, nor was there any possibility of allaying this strange terror until some persons called out that the enemy's cavalry were amongst them, when the soldiers mechanically ran together in masses, and the illusion was instantly dissipated."

The following, related by Southey, in his Peninsular War †, strikingly illustrates the effects produced on animals by an union of acquired discipline and the instinct of imitation. It occurred on the embarkation of the Spaniards under the Marquis de la Romana:—

"Two of the regiments were cavalry, mounted on fine, black, long-tailed Andalusian

horses; these, about one thousand one hundred in number, it was impracticable to bring off, and Romana was not a man who could order them to be destroyed lest they should fall into the hands of the French. He was fond of horses himself, and knew that every man was attached to the beast which had carried him so far and so faithfully. Their bridles, therefore, were taken off, and they were turned loose upon the beach. As they moved off they passed some of the country horses and mares, which were feeding at a little distance. A scene ensued such as probably was never before witnessed. The Spanish horses are not mutilated, and they were sensible that they were no longer under any restraint of human power; a general conflict ensued, in which, retaining the discipline they had learnt, they charged each other in squadrons of ten or twenty together; then closely engaged, striking with their fore feet, and biting and tearing each other with the most ferocious rage, and trampling over those which were beaten down, the shore, in the course of a quarter of an hour, was strewn with the dead and disabled. Part of them had been set free on a rising ground at some distance, but they no sooner heard the roar of battle, than they came thundering down over the intermediate hedges, and, catching the contagious madness, plunged into the fight with equal fury. Sublime as the scene was, it was too horrible to be long contemplated, and Romana, in mercy, gave orders for destroying them."

I shall now pass to another part of my subject, the varieties of the human race. This matter has been so fully discussed by Lawrence and Prichard (whose works I would strongly recommend you to peruse), that very little remains for me to remark.

In the human species we observe very remarkable varieties as to conformation of body, peculiarities of size and form, and particularly with respect to the colour of the hair, eyes, and skin. There is a vast difference in point of colour and appearance between the negro tribes and the inhabitants of England, Germany, and Denmark. You will find that most authors have agreed in dividing the human species into certain races according to some shades of colour which preponderate. Thus we have the fair, comprising the Europeans and Circassian variety; the black, which includes all the negro and negrite tribes; and the copper colour, which prevails in North and South America, a part of Africa, and a portion of China; and, lastly, we have the olive tribes of Asia, including China and the northern parts of Hindostan.

I shall not enter into any detailed descriptions of these tribes; I used formerly to lecture on these subjects more fully, but find I cannot at present spare time for that purpose, and beg leave to refer you to the works already alluded to. I shall merely mention one fact, also dwelt upon by Dr. Prichard, namely, that none of these tribes constitute a distinct spe-

* Vol. III. c. vii. p. 327.

† Vol. II. p. 345.

cies; it is much better to call them varieties. We find that all have been for a very great length of time distinct from each other; thus black and red skins have existed from the earliest historical eras. This is proved by the paintings which exist on the walls of the Egyptian temples, in which we observe these two colours carefully distinguished. If we can place credit in the Chinese records, the olive race must also be of great antiquity; and the same must be allowed of the Jews, Greeks, and Persians of the white race.

Some physiologists have contended that where you find any particular race flourishing it is quite in vain to endeavour to plant another there very different in character from the native of the country. Thus, if a country be filled with black aborigines, it is quite useless to attempt to colonise it with whites, and they point to Sierra Leone as an example corroborating their views. They assert that if you take a country inhabited by any intermediate race between the white and black, as, for instance, the red or the olive, you may, with some hopes of success, plant either of the extremes in that country, and they refer to the facility with which both whites and blacks become naturalised to the climate of America. This conclusion has a great appearance of plausibility, but it is not borne out by the fact. At very remote historical eras, various red and black tribes existed in Africa, and they still subsist there, while an addition has been made since the Hegira by the introduction of the white Arabian race; thus at present we have three distinct shades of colour coexisting in Africa. Two of them have been living together from the most remote antiquity, and the white has been settled among them for the last 1100 years.

It is not merely by colour that the different varieties of mankind are distinguished from each other. Most of you are aware that the negro differs from the European not only in the colour of his hair and skin, but also in his skeleton, in the form of his skull, in his spine, his ribs, and his superior and inferior extremities. There can be no doubt that the European has a more highly developed organisation, so far as the skull is concerned, and that its form possesses great advantages over that of the negro. This distinction is quite obvious on a slight inspection of the skulls of each, and you can tell at a glance, by its low and retreating forehead, that this belonged to a negro.

Inasmuch, therefore, as the cranial organs of the white or European race are found to be more fully developed than those of other nations, many authors have been led to the opinion that they possess an intellectual superiority over the rest of their species, and that the history of mankind furnishes ample proof of this assertion. We have already seen what imperfect instruments, and how little calculated to promote the spread of knowledge, many of the languages spoken by the black,

red, and-olive races are, and I think it may be fairly questioned, whether this and other accidents of a similar tendency have not contributed to retard the intellectual progress of such nations whose deficiencies we are wont to attribute, not partly to co-operating causes, but entirely to a supposed want of development in the cerebral mass. History informs us that science first dawned upon Egypt, that it was there the first seeds of civilisation were planted, and that it was from Egypt that the science and literature and arts of antiquity were transplanted into Western Asia and Europe. And, what is still more remarkable, there are strong and almost certain proofs that the Egyptians received their learning and their civilisation from the black or Ethiopian race; indeed Mr. Prichard seems to have established this fact beyond contradiction. Here then is a fact contrary to the general opinion, that the European variety has always surpassed the other races in the career of literature and science. The cradle of European literature lay in Greece, which, it has been fully proved, derived the greater part of its learning from Egypt, and this in its turn from the black tribes inhabiting Ethiopia. It should also be remembered, that literature and science in China were for many centuries in a far more advanced state than they were at the same periods among the European nations.

I may observe, that with respect to the black and white varieties of mankind, the habits which distinguish them are, like their colour, hereditary. Thus it might be supposed that the children of European parents, born in a warm climate, from being habituated to it from the moment of birth, would be far better able to bear it than their parents. Such, however, is not the fact. The children of English, French, and Irish parents bear a warm climate very badly; they languish during infancy, and frequently die before they attain the age of puberty, so that, in order to secure a certain degree of power in the constitution, it is frequently necessary to send them back to Europe. On the other hand, children born in the Indies, and of a stock intermediate between the Hindoo and the European, participate in the qualities of both, being in body as active and healthy as the Hindoo, and in intellect as distinguished as the European. There is no way in which the crossing of breeds has been so successful in producing a vigorous and intellectual race as between the European and the Indian.

It appears that many habits, physical as well as moral, are to a very remarkable extent hereditary; of this I could bring forth numerous instances. The hereditary tendency to certain moral or immoral habits in particular persons has been long known; and it has been frequently remarked that the offspring of such individuals share in the same tendencies, and are exposed to the same dangers in passing through life. The same hereditary resemblance exists also with respect to certain habits of

body. Thus, if the parents are accustomed to the use of a certain species of aliment, the same will be found to agree with their offspring. Our infants would soon sicken and die, if obliged to take the food on which the infants of the Greenlander and Esquimaux subsist and thrive. I was intimate with the late Sir Charles Giesecké, Professor of Mineralogy to the Dublin Society, who had spent some time in Greenland, and he told me that he has often seen sucking infants, five or six months old, lying at the bottom of a boat, while the parents were engaged in fishing, seize on a piece of blubber or stinking fish, and suck and swallow it with avidity, nor has he ever known any bad consequences to ensue from the use of such apparently improper aliment. I need not say that a very small portion of such substances would act as a kind of poison on one of our Irish children, whose parents feed on milk and potatoes. This is an interesting subject for consideration, and is worthy of being borne in mind by the practical physician.

The form of the head differs very considerably among the various races of mankind, but in none is it so remarkable for its peculiarities as among the Carribean tribes who inhabit the West Indian Archipelago and a portion of Continental America. Here, however, the very striking diversity of shape is owing, not to any peculiar natural conformation, but to the operation of artificial means, sedulously employed from the earliest periods of infantile life. You are aware that compression, if applied constantly during the period of growth, will prevent any part of the body from becoming fully developed. Hence, the Chinese, who confine the feet of their female children in iron boots during the period of growth, succeed in producing those wonderfully small and distorted feet on which their fine ladies hobble. A somewhat similar mode, and for the same fashionable purposes, has been adopted with respect to the head by the Caribs. If compression was carefully and constantly applied to the head on all sides, the growth of the cranium and brain would be obstructed, and the individuals experimented on might have amazingly small heads, as the Chinese have small feet; but even if it were possible for such persons to arrive at full growth and maturity, the necessary consequence of such compression would be to make them idiots. However, it is possible to modify the shape of the head very considerably without inflicting any great or abiding injury on the mental faculties, by applying compression in a particular way, so as to make the skull assume a different shape from the natural one, without lessening its volume or that of its contents. Some of the Indians, hence called *Flatheads*, compress the skull laterally, and by this means the head is made to assume a flattened and elongated shape, so that a line passing from beneath the chin to the vertex, instead of being seven or eight

inches, is nearly twice that length. I need scarcely add, that the origin of this disfigurement is to be traced to that all-pervading principle—vanity, a flat and elongated head being looked upon by the Indians as an unequivocal mark of nobility and beauty. Other tribes compress the head backwards and downwards, so as to make it project posteriorly in a very curious manner. Which of these modes is the most physiological I cannot venture to pronounce, but they certainly succeed in altering the shape of the skull and brain to a very considerable extent, and, what is equally curious, this unnatural treatment does not appear to interfere much with the development of their intellectual faculties. It would appear that, though the natural shape of the brain is changed to a very considerable extent, still this organ retains its usual size and weight. I mention these facts, because, at a late meeting of the British Association at Edinburgh, there was a debate as to whether some skulls dug up in Mexico did or did not belong to an extinct race, because they happened to be shaped in a curious manner, similar to that now spoken of.

I have already alluded to the fact, that the different races of mankind are adapted to different countries and climates, and that each lives longest in the country where it is either aboriginal or settled for a long course of generations. This law, however, does not seem to affect that race intermediate between the natives of two very different climates, as we see exemplified in the vigorous and long-lived breed which results from a cross between whites and negroes. It is a common saying, and an article of popular belief, that we in the north of Europe are healthier, stronger, and live to a more advanced age than the dusky inhabitants of the tropics. I do not think either of these assertions borne out by the truth. I believe that many of the black tribes of Africa are as robust and as powerful men as either the Swede, the German, or the Englishman. The descriptions given by Clapperton and Denham of the blacks inhabiting the interior of Africa are quite sufficient to prove that they are possessed of great bodily strength and uncommon vigour of constitution. Major Denham mentions that on one occasion, having to cross over a slippery and dangerous chasm, he was under the necessity of having himself carried by one of the natives; and he says that, while mounted on the brawny shoulders of this gigantic negro, he could not help feeling his own deficient strength, as compared with that of his guide, who carried him with as much apparent ease as a woman carries an infant. With respect to longevity, we do not find that in this respect either do the whites possess any advantages over their dusky fellow-men. You are aware that in North America the two races have subsisted together for a considerable length of time, and that, although some late acts of the government

have removed many of the disabilities under which the black population laboured, still their intermixture with the whites is by no means extensive. However they sometimes do, and their children are much in the habit of intermarrying. Now it is a curious fact that this mixed breed, forming the different varieties of mulattoes, are not only an intellectual race, but they are also remarkable for their bodily vigour, and, in particular, for their superior longevity. According to a late census of the population of the United States, it appears that of 20,000 whites only one arrives at the age of 100, of the blacks only one out of 1400; while among the mulattoes, one out of every 500 attains the age of an hundred. This seems very strange, particularly to those who suppose that no constitution can equal that of the European or white in vigour and durability; however, there can be no mistake in the matter, for the facts I have mentioned, are taken from an official census. Here, then, we have evidence sufficient to overturn the erroneous notions which prevailed with respect to the comparative longevity of the black and white races; for we find that in America, a climate which would appear equally suited to all, the black is longer lived than the white, and the mulatto than either. One would be led to imagine that the mixture of black and white would give rise to a mongrel breed, possessing neither durability nor strength of constitution; but this is not the case, for we find that forty times as many mulattoes become centenarians as we can meet with in the same number of whites.

With respect to the structure and development of the body of the new-born infant, I shall say but very little at present. I have already alluded to the development of the brain in infants, and dwelt on its peculiar adaptation, at that period, to the purposes of knowledge. Nature has been at particular pains in preparing the brain, so as to facilitate the progress of intellect as much as possible, and hence we find the child gifted with very remarkable powers of perception, memory, and imagination. Along with the brain and nerves we have the digestive system also in a state of very high development, it being necessary that the digestive functions should be performed with great activity, in order to supply a sufficiency of materials for the increase and growth of the body. With this view, also, there exists at this period a considerable degree of energy in the respiratory and circulating systems, but, after these, the remaining portions of the system seem to possess but little power, and are destined to remain in the back ground for some time. Thus we find the organs of locomotion and voice more or less imperfect. The bones are soft and flexible, and have not sufficient firmness for supporting the weight of the body; the muscles are weak and delicate, and, as yet, unaccustomed to obey the will; the limbs are short and small, and the larynx incapable of those motions which are necessary for the formation of articulate

sounds. The adaptation of all these arrangements to the peculiar circumstances of the infant, is sufficiently obvious, and requires no comment. It should be observed with respect to the body of the infant as compared with that of the adult, that not only are the bones softer, but also the brain, blood-vessels, and cellular membrane, in fact, the whole flesh is softer, and, to put the matter in a stronger point of view, the specific weight of the infant is smaller than that of the adult, and of the adult than the aged. Again, the bodies of infants are composed of materials less highly animalised than those of adults at the mature period.

You will recollect, then, that in the firmness and specific gravity of its textures the infant falls short of the adult, and the adult of the aged. As old age creeps on, there is a tendency in the fluids to diminish in quantity, and the solids to become firmer and denser in their structure, and as this progresses from day to day, and from year to year, the inevitable consequence is, that our organs become less and less adapted to the performance of their functions, and life ceases.

The weight of a male infant at birth is, on an average, about seven English pounds. On this point I need not take up your attention, for you will find the matter treated in detail in your works on midwifery and medical jurisprudence. You will find some very interesting observations on this point, which were made by a Flemish investigator, Dr. Quetelet, and which have been translated in Jameson's Journal. There is one curious circumstance connected with the weight of children at birth, which was first noticed by Chaussier, and has been since confirmed by the researches of Quetelet, viz. that the weight of a child diminishes for some days after birth (slightly however), and that it does not begin to exceed the weight at birth until after the first week. Girls, as you are all aware are lighter than boys at the period of birth, and they continue so until they approach the age of puberty, when they begin to gain on boys in point of weight, so that at twelve a girl becomes as heavy as a boy of the same age. The cause of this rapid increase in growth is the earlier puberty of the female sex. The adult continues to increase in breadth long after he ceases to grow in height: his flesh, also, becomes more solid, and he generally arrives at his maximum weight at forty. After sixty he begins to decline and lose sensibly in his weight; and if he should survive to eighty, he will have lost about one-ninth of his maximum weight, and, along with this, he will be found to have reduced (according to the French measurement) about seven centimetres of his height. Hence there appears to be some truth in Nestor's remark, that he was neither so bulky nor so tall as in the days of his youth. In women, the period of arriving at the maximum of weight is different. They continue, generally speaking, stationary as to weight

from the age of nineteen until the period of bearing children is passed, when they begin to increase rapidly in weight, and ordinarily attain their maximum at fifty. On an average, it appears from some calculations which have been made, that at the heaviest the adult weighs something about twenty times as much as at birth. With regard to the weight of children at different periods, it would appear that it is influenced very considerably by the greater activity of the digestive powers in the earlier stages of infancy, for, one year after birth, the infant will generally be found to have tripled its weight. At seven, they only weigh double what they did at one, and they do not quadruple the weight of one until they arrive at fourteen.

This rapid increase of growth under the operation of highly energetic nutritive powers, furnishes a very striking proof of the great activity of the digestive organs, and we know that in proportion to the activity of an organ is its liability to disease. This shows that most of the diseases of children will be of a gastro-intestinal character, and that our principal remedies will be aperients, emetics, and medicines calculated to relieve intestinal irritation. In fact, every organ in the child (particularly those most important to life) is in a state of high vascularity; and this predominance of fluids circulating in vessels having all the characters of energetic vitality, is necessarily accompanied by a tendency to inflammation, and hence the rapidity with which inflammatory affections attack the organs of children. As the impetus of the circulation is also directed with great force towards the periphery, we can easily explain why the skin of the child is more vascular than that of the adult, and why cutaneous diseases should be more numerous, more extensive, and more rapid, in the child than in the adult. To illustrate this, I need only give a single example. In the adult, itch sometimes appears and puts on either a vesicular, or papular, or pustular appearance (I disagree with M. Biet, who asserts that it is always vesicular); but, unless the individual be a person of filthy habits and totally neglects it, its progress is but slow and its extent inconsiderable; in fact, it is almost exclusively confined to the spaces between the fingers, and the insides of the joints. The face and scalp almost always escape. But in the infant its course is very different; it spreads with great rapidity, not sparing either the face or scalp, and in the course of a few days the body is covered by a cutaneous eruption. The skin cracks and oozes a serous fluid, and this, combined with the intolerable itching, renders it a very annoying or even dangerous complaint. All these differences are accounted for by the physiological differences of the skin, which, as you are aware, is characterised by high vascularity and irritability during the period of infantile life.

With respect to the circulation and respiration of the child, it may be remarked, that

they are carried on with great energy; the heart and lungs are small, but they make up for this by an increased activity. The pulse is quick, and the action of the lung is intense in proportion to its size; and hence Laennec, in distinguishing that state of respiration in the adult where the function is carried on with unusual energy, has termed it *puerile respiration*. The investigations of modern physiologists, which have naturally followed the important discoveries of Laennec, have elicited some curious facts respecting the circulation in the earlier periods of life; and have shown, that before birth the pulse is uncommonly quick, amounting to 160 in a minute. It has been lately ascertained, at Berlin, that the approach of a labour pain may be foretold by a person who keeps the stethoscope applied to the abdomen of a parturient woman by means of a marked acceleration of the heart's action for several seconds before the pain commences. This shows a remarkable connexion between the vital actions of the fœtus and those of the mother, and is well worthy of observation.

It is not my intention, gentlemen, to speak of the motions of the fœtus in utero. The impulse of different portions of its body against the uterine parietes is felt plainly by the mother, and can be even distinguished by the eye*. That they result from any exercise of volition on the part of the fœtus appears extremely improbable; some circumstances have led me to think that they are of an involuntary and spasmodic nature, similar to the irregular muscular motions that take place in every one when falling asleep. As the fœtus, when born at seven months, or even earlier, is capable of awaking, it is obvious, that for the last two months of its sojourn in utero, the state of its nervous system must be something similar to what it is after birth at the usual period of nine months. Whether it truly sleeps, or whether it awakes at times, will never be ascertained.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XVI.

Retroversion of the Uterus—Extra-Uterine Pregnancy.

GENTLEMEN,—At my last lecture I concluded my observations on the signs of pregnancy.

* These are not to be confounded with the motions produced by sudden changes of shape in the uterus itself, and which take place equally in the pseudo-pregnancy occasioned by hydatis and other causes.

You would, perhaps, at the first thought, expect that I should now proceed to describe that process which terminates pregnancy, viz. labour, but before I do this, there is a variety of deviations and derangements, to which pregnancy is liable, which it will be necessary for me to consider before describing labour itself.

During the earlier months of pregnancy the uterus is liable, although rarely, to a very peculiar displacement, called *retroversion*, where the fundus is forced downwards and backwards between the sacrum and posterior part of the vagina, while its cervix and mouth are carried forwards and upwards towards the symphysis pubis.

This is a disease which, in many instances, depends upon the connexion of the uterus with the bladder, which is so intimate by means of the peritoneum and cellular substance, that whenever the bladder rises by distension, the uterus must rise also. Now, as the bladder is globular, and the point of adhesion, between the two organs, is only at the inferior part, it follows that the uterus must go off at a tangent from the globe of the bladder, its fundus being thrown further back, at the same time that its orifice is carried higher up. This happens in every case of retention of urine. It is evident, that if, during this position, pressure be made from above on the fundus uteri by the intestines, or if the fundus contain any thing which makes it heavy, it must be pushed lower down, by which the uterus will come either to lie horizontally across the pelvis, or may be turned completely upside down. This does not often happen to the unimpregnated uterus, because in that state there is seldom any sufficient gravitating cause applied to the fundus, but in gestation there is a period in which the fundus becomes sufficiently heavy from the ovum, which it contains, and yet is not so much distended as to prevent its being turned down into the pelvis; this period is about the third or fourth month, often before it but never after it.

Besides this cause, which produces a sudden and immediate retroversion of the uterus, this disease may likewise be produced by the uterus remaining too long in that situation, which is natural to it when impregnated, viz. with its fundus inclined backwards; this may depend on various causes, such as too great width of the pelvis, or the pressure of the ilium full of fæces on the fore part of the uterus. In this case the weight of the fundus must gradually produce a retroversion, and we shall be sensible of its progress from day to day, whereas the other takes place suddenly. In this disease, by introducing the finger into the vagina, we ascertain that the os uteri is raised much higher and thrown more forward than usual, so that sometimes it cannot even be reached; by the same means, or by the finger in ano, we discover a hard tumour, formed by the fundus uteri, pretty low down, between the vagina and rectum. - These are the distinguish-

ing marks of the disease, and we are led to suspect its presence by the following symptoms:—there is a sense of fulness and weight at the fundament, tension in the groins, and inability to void either urine or fæces, owing to the pressure on the neck of the bladder and rectum*. When such suppressions once begin they aggravate the evil, not merely by causing pain, but by occasioning a load of accumulated urine and fæces above the uterus, which presses it still lower into the cavity of the pelvis, at the same time, as I before mentioned, the distension of the bladder in this state draws up that part of the vagina and cervix uteri, with which it was connected, so as to throw the fundus uteri still more directly downwards†. These conditions of the bladder and rectum, and the retroversion of the uterus, act reciprocally as cause and effect, for the continuance of the distension of the bladder, and the descent of the fæces from the part of the intestine above the obstruction, must elevate still more the os uteri, and depress to a still greater degree the fundus; the retroversion, on the other hand, increases the affection of the bladder and rectum, from which the principal danger of the disease arises.

In this plate of Dr. Hunter's work (*showing it*) you have a very instructive view of the relative position of the parts in retroversion. In the first figure you see the enormously distended bladder, reaching nearly up to the scrobiculus cordis, and concealing every thing behind it; on cutting this open, as in the 2nd figure, the posterior wall of its cervix is pushed forwards, evidently from some projecting body behind, this, on incision, shows to be the os uteri tilted up against the neck of the bladder, and pressing so forcibly against it as to prevent the urine from escaping. In the posterior view you see the large globular mass of the fundus turned completely into the hollow of the sacrum, and compressing the rectum so as to flatten it and render it quite impervious. I know of no other plate extant which gives so clear and excellent a representation of this displacement.

This disease may be mistaken for a prolapsus uteri, but can be most easily distinguished from it. Firstly, by the vagina in retroversion interposing between the finger and the tumour, and the neck of the uterus being mounted up behind the symphysis pubis.

2dly. By the absence of the neck of the uterus, which is always felt in advance of the body, and fundus in prolapsus.

3dly. The symptoms never being so extreme in prolapsus, and are generally, if not always, relieved by assuming the upright posture.

4thly. By the prolapsed uterus always being moveable, the other obstinately fixed.

According to Mr. Burns, it may also be confounded with a diseased ovarium, when it may chance to occupy this place, or with an

* Burns.

† W. Hunter.

extra-uterine conception, when it may have been found between the rectum and vagina. "We believe (says Dr. Dewees) it may serve to distinguish between these two complaints, by noticing that in both the diseased ovarium and extra-uterine conception, the neck of the uterus is always within reach of the finger; we may also observe that both ovarian tumours and extra-uterine conception, are of slow and regular progress, especially, perhaps, the latter."

The cure consists in emptying the intestine by clysters, and removing the distension of the bladder by the catheter, whilst we attempt to push up the fundus with the finger; but our great object is first to procure the evacuation of the urine, after which the rest is more easily accomplished. The catheter should be employed *pro re natâ*, and the bowels emptied daily, either by medicine of a mild kind, or by injections. If this plan should not succeed in restoring the fundus, we should then maturely consider the propriety of mechanically replacing it. To aid us in our judgment we should consider, 1st, the period of gestation; 2ndly, the degree of development the uterus has undergone; 3rdly, the nature and severity of existing symptoms. The period of gestation should almost always influence our conduct in this complaint, and we may lay it down as a general rule the nearer that period approaches four months, the greater will be the necessity of acting promptly in procuring the reduction of the fundus. The reason for this is obvious; every day after this will but increase the difficulty of the reduction from the continually augmenting size of the ovum.

The degree of development should also be taken into consideration, as some uteri are as much expended at three months as others are at four. Consequently, when this is the case, there is a decided reason for acting earlier than may at other times be necessary. So also at the fourth month, if the development be less than is usual for that period, we may, *cæteris paribus*, delay the attempt at reposition, if any reason present itself to make this eligible. The extent or severity of the symptoms must ever be kept in view, as, for instance, where the suppression of the urine is complete, and not to be relieved by the catheter, in consequence of the extreme difficulty or impossibility to pass this instrument; here we must not temporise too long, lest the bladder become inflamed, gangrenous, or burst; for the bladder, from its very organisation, cannot bear distension beyond a certain degree, or beyond a certain time, without suffering serious mischief*. "There are few facts (says Dr. Dewees) of which we are more certain, than that a certain degree of distension of the bladder may exist for a considerable time, and even where we have been under the necessity of using the catheter, without producing retroversion, and we are also certain in retroversion that the

mere removal of the urine will but rarely, nay not once, perhaps, in ten times, where the complaint is of long standing, or the pregnancy be advanced beyond the third month, be sufficient to ensure the spontaneous or artificial reposition of the uterus."

In passing the catheter under these circumstances, as also whenever there is any peculiar difficulty, it is better to use the elastic catheter in preference to the silver one, as being not only the easiest to introduce, but also safer. And now that I am upon the subject, gentlemen, I will digress for a moment, and give you a few simple rules for using this instrument. Nothing is more simple than passing the female catheter, on account of the shortness of the urethra, and yet, to the beginner, nothing is more perplexing and difficult; and this is the more annoying to him, because he knows that it is an operation which he will be frequently called upon to perform in private practice, and where it must be done entirely by the guidance of his finger, unaided by the eye. The rules which are commonly given to find the orificium urethræ are, to my mind, very unpractical, and I do not hesitate to confess to you that I found them of no use in removing the difficulty when I first tried to pass the female catheter. I remember feeling much annoyed at not being able always to succeed in finding the orificium urethræ, and mentioned the grievance to my friend the late Dr. Gooch, who gave me the following directions, which I found of great service, and give them you nearly verbatim.—First pass your finger a little way into the vagina, you then know the relative situation of the parts; under the pubal arch you will feel the firm cord-like mass of the urethra, and, sliding your finger along it towards its anterior extremity, you cannot fail to find the orifice. The catheter should not be carried further into the bladder when the urine begins to flow, unless it ceases before the distension is removed, which, in some cases, happens in such a manner as to give us the idea of a bladder divided into two cavities. External pressure upon the abdomen will favour the discharge of the urine, after which the patient is sensible of such relief as to conclude that she is wholly freed from her disease*. In urgent cases, where the above mode of treatment has not succeeded in restoring the uterus to its natural position, Dr. W. Hunter asks if "it would not be advisable, in such a case, to perforate the uterus with a small trocar, or any other proper instrument, in order to discharge the liq. amnii, and thereby to render the uterus so small and lax as to admit of reduction." This practice has been attempted in a few instances; and an interesting case is recorded by Mr. Baynham, where the retroverted uterus was successfully punctured. The real nature of the disease had not been ascertained for six weeks, the catheter only being used night and morning.

* Dewees.

* Denman.

Even when the bladder was empty the fundus resisted every attempt to return it. The most prominent part of the tumour in the rectum was punctured by a trocar, and about $\frac{3}{4}$ xij. of liq. amni, without blood, were drawn off; the reduction followed in a quarter of an hour; a full opiate was given, and the patient passed a better night than she had done before. Twenty-five hours after the operation the fœtus was expelled, fresh, and of the size of a six months' child. The patient recovered.

One of the greatest difficulties with which we have to contend, are the violent and involuntary efforts to bear down, to which the woman is excited by the presence of the hand in the vagina, and we may thus be foiled in our attempt at reduction, although we have succeeded in evacuating the bladder and the rectum. To overcome this opposition, experience (says Dr. Dewees) has repeatedly taught us the efficacy of bleeding to or near to fainting. "When we have determined upon the bleeding, we should be prepared beforehand to take advantage of the deliquium, as its effects are but transitory. The bed should be prepared in such a manner as will allow the patient to lie upon her back with the perineum free over the edge of the bedstead, and her shoulders a little depressed. The parts should be well lubricated with lard or oil; a chair should be placed for each foot to rest on, and these supported by two bystanders; when every thing is in readiness, the arm should be tied up (the patient standing near the bed), a large orifice should be made, and the blood drawn until the faintness is induced; when this happens the arm must be secured, and the woman placed as just directed. The hand, well lubricated, should be passed into the vagina in a state of supination, and the fingers gently pressed against the base, as it were, of the tumour that is found within the vagina, so as to move it backwards and upwards along the hollow of the sacrum, until the mass shall reach above the projection of this bone; when thus far the hand may be withdrawn, and a pessary introduced of a proper size; the woman should remain quietly in bed for three or four days, the urine should be drawn off as often as may be required, and the fœces evacuated by injection.

Where the uterus has become retroverted, and has not produced much inconvenience, and has been allowed to continue for some considerable time, it becomes at last impossible to reduce the uterus on account of the large size of the fœtus. In some of these cases pregnancy has gone on nearly to its full period, violent pains have come on, and the child has been discharged into the vagina through an ulceration in the side of the uterus.

As these cases were for some time mistaken for extra-uterine conception, I shall delay any further observations on them until I come to speak of that subject.

The uterus is subject to another, though much rarer displacement (at least in the gravid state), called *anteversion*, where the fundus falls forwards against the posterior wall of the bladder, the os uteri being turned backwards into the hollow of the sacrum. A partial state of anteversion is not a very rare affection in the unimpregnated state, and appears (at least in the cases which I have seen) to be connected with some menstrual or gastric derangement. The chief symptom which leads us to suspect its presence, is inability to hold her water for any length of time, accompanied with much straining and forcing about the region of the bladder, and chiefly alleviated by the supine posture. I have never seen anteversion of the *gravid* womb but in one instance, and in describing the history of this case, I think I shall thus put the diagnosis of anteversion in the clearest point of view before you.

Mrs. F——, æt. 26, married four months, reckons that she is six weeks with child, no catamenia having appeared since then. Was seized ten days ago with great pain about the bladder, attended with constant inclination to make water, and straining as if she wanted to pass more; this pain returned yesterday with much severity, and a smart discharge of blood, accompanied with some coagula made its appearance; the pain has come on in fits, and there has been much sickness of stomach and some vomiting, with considerable oppression at the præcordia. Bowels costive, pulse slow and soft, countenance anxious and pale, is sleepy just now from the effects of an opiate glyster. Says that she has been frequently liable to a difficulty in retaining her water for any length of time, which has come on occasionally for some years before her marriage.

On examination per vaginam, I felt a hard body above the upper wall of the vagina, nearly in the situation of the neck of the bladder when much distended, the superior portion of the vagina was stretched, evidently by being pulled backwards. I could distinctly feel where it became united with the cervix uteri, but there was none of that cul de sac which one usually feels on examining the upper part of this canal, at the spot where its mucous membrane is reflected upon the cervix uteri; on the contrary, it formed a straight surface running backwards. On passing my finger backwards, I found the os uteri in the hollow of the sacrum so completely directed backwards, that I could only reach its anterior lip; being therefore convinced that it was the fundus which I had felt anteriorly, I pressed it upwards pretty firmly; the os uteri now came within reach, it was open enough to admit my finger with ease, and, using my finger as a blunt hook, I gently pulled it forwards; the uterus distinctly swung round, the tumour at the back of the neck of the bladder disappeared, and the os uteri returned to its natural situation. My examination produced a slight discharge of blood, but she had lost the painful.

want to empty the bladder, nor did she feel now the dragging in the neighbourhood of the broad ligaments from which she had before suffered. ℥ x. of liq. opii. sed. and ℥ xx. of spiritus ammon. aromat. were given in a draught, and she was directed to lie upon her back and keep her knees up. I saw her the next day; she had passed a comfortable night; the fundus and os uteri, &c., were in their natural situation; there was scarcely any discharge, the pulse stronger, and she was in good spirits. There was considerable doubt entertained by my friend, Mr. M. Wagstaffe and myself, whether abortion had taken place or not, several coagula were discharged, but we could find no traces of an ovum. I saw the patient no more, and have since lost sight of her; but, at the time when I drew up this case, from the size of the fundus and general condition of the os uteri, I felt convinced that she was not only pregnant, but that in all probability the ovum had not been expelled.

I now come, gentlemen, to the subject of *extra-uterine pregnancy*. The ovum does not always, when impregnated, quit the ovary and pass through the Fallopian tube into the uterus. It may remain in the ovary and become here developed, it may pass into the Fallopian tube and there remain, or, from some defect in the action of the fimbriated extremity of this canal, it may escape into the cavity of the abdomen, and become there attached to some viscus; hence, extra-uterine pregnancy has been divided into three species, viz.—*graviditas ovaria, tubaria, and ventralis*. Besides these, M. Breschet has observed another species of extra-uterine pregnancy, which he calls *graviditas in substantiâ uteri*.

This singular deviation from the usual course of conception is fortunately of rare occurrence, for few cases terminate favourably. It is seldom discovered during the first months of pregnancy, for at this early period it is scarcely possible to distinguish it from natural pregnancy. If it be in the Fallopian tube or ovary, these become immensely distended into a species of sac or cyst, to the sides of which the placenta adheres; as the ovum increases this at length gives way from excessive distension, and the patient usually dies from internal hæmorrhage. The *graviditas ventralis* undergoes a similar termination at a later period, the placenta in this case being generally attached to some of the intestines. Of the four cases of *graviditas in substantiâ uteri* which have been observed, none have exceeded three months in point of duration.

Although the uterus does not receive the ovum into its cavity as it does in natural conception, it nevertheless undergoes many of those changes which are known to take place in regular pregnancy. The peculiar layer of coagulable lymph which is effused upon its internal surface, and which forms the membrana decidua of Hunter, is present, and the uterus undergoes a slight increase of volume.

As the ovum increases, excruciating pains are felt in the lower part of the abdomen, coming on at irregular intervals and of irregular duration, in some cases lasting for a short time, in others continuing for twenty-four hours. These attacks of pain are almost always accompanied with very painful forcing and tenesmus, and not unfrequently with a discharge of bloody mucus from the vagina. The tone of the crying and moaning, which the patient can seldom repress, is quite peculiar, so much so, that, once heard, it can never be mistaken in any succeeding case of this sort: the face is pale, and expressive not only of the most acute suffering, but of great anxiety and mental depression. Nevertheless, in the intervals of the attacks, she feels perfectly easy, and appears well and cheerful. During the attacks, there is obstinate constipation, which is attended with painful and fruitless efforts to evacuate the bladder and rectum.

The peculiar tone with which the patient expresses her sufferings was first noticed by the celebrated Heim, of Berlin, one of the most acute observers and accurate symptomatologists of the present day. By this symptom *alone* he has been enabled to detect the presence of extra-uterine pregnancy the instant he entered the patient's chamber, and before he had asked her any questions. Dr. Heim, who has had occasion to observe during his long and useful life very many cases of extra-uterine pregnancy, never found a case of tubarian pregnancy to last beyond two months, whereas ovarian and ventral pregnancy would last much longer, the former extending to five or six months' duration, the latter beyond the full term of common pregnancy.

In these cases the treatment consists merely in alleviating the pain by powerful doses of opium, during the paroxysms, and attention to the state of the bowels in the intervals. A putrid sanious discharge from the vagina frequently occurs, and arises probably from a separation of the decidua. In this manner the unfortunate patient is subject to occasional attacks of these pains, until, after a paroxysm more than usually severe, and frequently attended with the sensation of something giving way in the abdomen, faintings come on, speedily followed by death.

Although the symptoms, in the very earlier stage of extra-uterine pregnancy, are so obscure as to render it nearly impossible to detect its existence, still Dr. Heim has observed some facts connected with it, which are peculiar, and deserve to be noticed, *no morning sickness has been remarked in cases of extra-uterine pregnancy*; the patient could only lie upon the affected side, and the abdomen was observed to swell irregularly, not in the manner as in regular pregnancy. In tubarian and ovarian pregnancy, the pain was in the pelvis, but in ventral pregnancy it occupied more or less the whole abdomen, the parietes of which were very tender upon pressure; the symptoms of this last species of extra-uterine preg-

nancy were not unlike those produced in both sexes by perforation of the stomach, intestines, or œsophagus. In cases where the foetus died at an early period, the symptoms gradually disappeared after a time, especially when followed by the bursting of an abscess through the rectum or any other part.

In some cases of ventral pregnancy, the foetus becomes enclosed in a cyst, and is thus carried for several years, frequently becoming more or less converted into a calcareous mass; of this there are many instances on record. In other cases the parts of the child are gradually discharged through an abscess in the parietes of the abdomen, or into the intestines.

A most interesting case of pregnancy occurred to my respected friend Dr. Heim; his powers of accurate diagnosis enabled him to decide *confidently* as to the nature of the case, and, when the pregnancy had gone its full term, *gastrotomy* was performed; a living child was extracted, but the unfortunate mother perished. She could not be induced to submit to the operation until the severity of her pains had already exhausted her. The intestines were found much inflamed, and before the child could be removed and the cord tied, they had become so swollen that it was found impossible to return them entirely. It would be taking up too much of your time to enter into all the particulars of this highly interesting case, but the examinations which were made by the late Dr. H. Meyer, and the results of the *sectio cadaveris* contain so many interesting facts connected with the pathology of extra-uterine pregnancy, that they cannot fail to afford much instructive information. "I found (says Dr. Meyer) the patient suffering from the most violent pain of the left side, below the umbilicus; the features peculiarly contorted, the pulse full, hard, &c. In six days after (18th March, 1812), after the violence of her pains had been relieved by bleeding and other appropriate remedies, I examined her. The abdomen (externally) was somewhat larger and more distended to the *feel* on the left side, without being peculiarly painful on moderate pressure; the vagina lay quite to the right side of the pelvis, but the os uteri was so high up that I was unable to reach it. To the left side of the pelvic cavity, I felt a distended tumour like a bladder full of water, of about the size of a child's head, her breasts were somewhat swollen. Four weeks afterwards (16th April), I again examined her. The abdomen was fuller and more distended, especially upon the left side, than it ought to be without the presence of pregnancy, and this was the case higher up than before, still not painful on pressure. On examination per vaginam I came at once to an oblong hardish body resting upon the os coccygis; it required some force to pass my finger between this body and the bone, but still without exciting pain, and having reached the os uteri I convinced myself that it was the uterus which had sunk into this situation.

The fundus was more to the right side, but larger, softer, and more cushiony than the cervix and portio vaginalis, which were also larger than in the unimpregnated state, but harder than usual. The distended tumour which I had felt the last time on the left side of the pelvis, was still quite distinct but rather higher. I could not distinguish any solid substance floating in it as one does in common pregnancy. After the lapse of four weeks I again examined her. She had distinctly felt the motions of the child; the abdomen on the left side had increased in size, but was not painful upon moderate pressure; the uterus was not so low down, and no longer rested upon the coccyx; the cervix was softer and more swollen; the vaginal portion still somewhat hard. The bladder, like the tumour, could still be reached, but was much higher; the breasts were as in common pregnancy at this time. In June the abdomen was larger; the motions of the child were quite distinct through the parietes of the abdomen; the uterus as before, except that only a small part of its portio vaginalis remained hard. I was accidentally prevented from examining in July. On the day of the operation (28th August), the uterus was very low in the cavity of the pelvis, with its fundus pressed towards the right side; the whole vaginal portion was soft, and the os uteri so dilated that the finger could pass up, without pain, full an inch, where I could distinctly feel the child through the vagina, on the left side, where I had formerly felt the tumour." "At the post mortem examination, on the 31st of August, it appeared that the child, which was a stout full-grown boy, had been enclosed in a large membranous sac, chiefly on the left side of its mother's abdomen, covering the internal surface of the left os ilium, and extending over the promontory as far as the cæcum. From this part it extended, with the small intestines before it, on the left side, as far as the spleen and the great curvature of the colon, on the right side, to where the duodenum passes into the jejunum: the small intestines were not at all connected with this membranous sac. On its internal surface, corresponding to the cæcum, was the placenta, in no wise differing from that of a common pregnancy. The Fallopian tubes and ovaries, excepting an incipient state of inflammation, were natural. The uterus itself was at least three times larger than usual, and also somewhat inflamed, the os uteri dilated, and the tunica decidua distinctly lining the cavity of the uterus."

It would appear from the observation of Dr. Merriman on this subject, that cases of retroversion of the womb, where pregnancy has gone on to the full period, have been occasionally mistaken for ventral pregnancy. The pains have come on, but the child, from being felt between the rectum and cervix uteri and vagina, has been considered as extra-uterine. An abscess has formed, which discharged its contents into one or other of these passages,

and portions of the fœtus have gradually come away, as in cases of extra-uterine pregnancy. From the history of several cases published as extra-uterine, he has shown that the symptoms were evidently those of retroversion of the uterus during the earlier months of pregnancy. The patient had been subject to occasional suppression of urine and difficulty in passing her fœces; these symptoms had gradually diminished as pregnancy advanced, the os uteri could not be felt, or if it were capable of being reached, was found high up behind the pubes, the head of the child forming a large hard tumour between the rectum and vagina. The condition of the vagina afforded strong evidences of the nature of the complaint. On introducing the finger in the usual direction, it was stopped, as if in a cul-de-sac, but on passing it forwards the vagina was found pulled up behind the symphysis pubis.

In some of these cases, the uterine contractions gradually restored the fundus to its natural position, the os uteri descended from behind the pubes, and the child was born after long protracted suffering. In others, which have been mistaken for ventral pregnancy, the fundus has inflamed and ulcerated, and the child has been gradually discharged piecemeal. From these facts, Dr. Merriman is inclined to deny the existence and possibility of ventral pregnancy *in toto*, but here I must differ from him most decidedly; if there were no other cases on record than the one which I have just quoted from Dr. Heim, it would be sufficient evidence that such a species of pregnancy may sometimes occur; the operation of gastrostomy, the examinations per vaginam by Dr. Meyer, and the dissection of the abdomen after death, preclude the slightest possibility of doubt as to its having been a real ventral pregnancy; the facts, however, of the uterus being able to remain in a retroverted state until the end of pregnancy, and the effects thereby produced, are of the greatest importance, and demand the attentive consideration of the practitioner.

LECTURES

ON

FORENSIC MEDICINE,

DELIVERED BY

DR. HAY GRAHAM,

At the Westminster School of Medicine.

LECTURE XIV.

Insanity, continued.

GENTLEMEN,—1st. *Monomania*.—In this form of insanity the delusion is sometimes of such limited extent, and the intellect so little impaired in every other respect, that the patient appears perfectly sound in his mind so long as his attention is not directed towards the subject on which he is deranged. This appa-

rent sanity becomes the more remarkable when the monomaniac preserves sufficient presence of mind to conceal those ideas which, though he himself believes them to be true, he is aware are considered false and ridiculous by others, and may, therefore, injure him in their good opinion. Generally, however, the mental derangement is not of such limited extent in these partial delusions, as, from the descriptions of some authors, we might be inclined to suppose; for all the thoughts of these patients being concentrated on the objects of delusion, they are unable to employ themselves in other pursuits. Usually, those friends and relations who were the most beloved are forgotten, or, if remembered, it is only to entertain the most unjust suspicions, and to accuse them under the most frivolous pretexts. From time to time paroxysms of nervous agitation, accompanied with a more general state of derangement, suddenly break out. In that species of monomania which is marked by a predominant passion, or set of ideas fixed on one subject, the intellect being at the same time disordered in all other respects, there is nearly an equal degree of insanity as in mania; the only difference between these two kinds of madness is, that in the one the patient is constantly occupied with the same subject, whilst in the other he wanders incoherently on every subject. The predominant or exclusive ideas of monomaniacs are more frequently connected with their passions or inclinations than with the perceptions, talents, or other intellectual operations. The predominant passion, or set of exclusive ideas, seems to be connected, in the first place, with the particular character or well-marked disposition of the individual when in health;—thus, when the ambitious man becomes insane, he fancies himself a king, an emperor, or even the Deity; thus superstition or an excess of devotion may lead to the monomania of religious zeal; the love of wealth may give the false idea of large territorial possessions or inexhaustible treasures; and thus intense application of the mind on any one subject may give rise to a corresponding insanity; hence it is, that with many, derangement appears to be merely a morbid exaltation or increased excitement of the predominant character. Secondly, these exclusive ideas seem to be connected with the exciting cause of the disease:—thus terror sometimes produces a state of continual fear and timidity, and the alienation is connected with the concomitant circumstances of the case; the victims of treachery and false friends fancy they are surrounded with enemies, snares, and dangers; long-continued disappointments and vexations frequently throw the unhappy individual into a delirium of desponding melancholy. Sometimes we see cases where the predominant ideas and passions are diametrically opposite to the usual character and disposition of the individual; as where prodigality gives place to avarice; the absence of religion to an excess of devotion; and gentle-

ness, modesty, and humanity, to cruelty, boldness, and ferocity. At other times there is no clue conducting to the cause of monomaniac delusion, either as connected with the habits and character of the patient previous to the invasion of the disease, or as connected with the exciting cause which threw him into such a condition. But, how rarely do we know the secret passions, and, still less, the secret thoughts, of man!

The following are the principal species or varieties of this disease:—1st, *pride* and *ambition* create *gods, kings, emperors*, and *prophets*. These individuals carry their heads high and thrown back, walk with a stately step, maintain a lordly air in their intercourse with those around them, affect grandiloquence of speech, surround themselves with the emblems of power or the insignia of their divine commission; they talk but little, deeming it derogatory to their dignity, therefore they are not communicative, unless when they condescend to speak of their power and dignity; they usually assume a tone of authority, never that of humility; in short,

“ They assume the God,
Affect to nod,
And seem to shake the spheres.”

They are always surprised or indignant that any one should presume to dispute the lawfulness of their pretensions, refuse to comply with their wishes or obey their injunctions; and especially resent the indignity of being obliged to submit to their confinement and the discipline imposed upon them.

2nd. *Vanity* and *self-love*, rather than pride and ambition, create imaginary *queens* and *princesses*. These patients appear more desirous of distinction, the precedence of rank and the homage of beauty or high birth, the glittering of trinkets or the splendour of dress, than greedy of power. They walk with a stately air, are condescendingly affable, and ready to bestow patronage and protection on such as approach them with obsequious deference. Thus, even in madness, the foibles of the sex appear.

3rd. Many women bewail in tones of deep despair the loss of the attachment and affectionate regards they previously entertained for their husbands, their children, their family, and their friends; and the more their reason has remained unimpaired, the more poignantly do they feel the horror of their unhappy condition,—that vacuity in their affections, which leaves the heart hopeless, and fills with bitterness the cup of life.

4th. Violent and excessive sexual desires sometimes form the principal character of the derangement; this salacity, or nymphomania, shows itself by frequent sighing, and singing love ditties; the eyes roll in wanton glances, the cheeks are flushed, the bosom heaves, and every gesture exhibits the lurking desire, and is enkindled by the flame that burns within. The disease is strikingly marked by the move-

ments of the body, the salacious appearance of the countenance, and the lascivious language of the lips.

5th. The more delicate sentiments of *love* form the character of another species of derangement, which is termed *erotomania*. Sometimes it is the much-wished-for object of affection, which concentrates every thought of the patient; at other times it is an undefined sentiment of love, ardently felt, but not fixed on any object, which vaguely occupies the imagination. Love combined with religion sometimes gives rise to the sentimental love of God, of our Saviour, and of angels; thus the senses may be lost by conceiving a passion for an inanimate object,

“ — a dream of love,
Shaped by some solitary nymph, whose breast
Longed for a deathless lover from above,
And madden'd in that vision.”

In all these cases the object of affection takes exclusive possession of the mind; it is seen, heard, and felt, is addressed, embraced, and embellished with every charm which an imagination insanely fertile can conceive. Erotomania, or the monomania of love, is more frequent with women than with men.

6th. Those labouring under the monomania of religion are afflicted with scruples of conscience, and remorse for their past conduct; the dread of future punishment and everlasting pain continually haunts their minds, and strikes them with terror and dismay; some even believe themselves predestined to damnation, and already in the power of the devil, which is called *demonomania*; others devote themselves to the strictest observance of every religious injunction, pass their nights and days in prayer, mortify their bodies with sackcloth and ashes, with fastings, and other ascetic exercises; others behold visions, receive divine inspirations, prophesy, and issue their mandates in the name of the Most High, who has given them his divine commission to warn the human race of impending ills, and to convert sinners from their evil ways.

7th. That monomania in which the sad and painful emotions of the mind predominate, such as the *tædium vitæ*, vexation, anxiety, fear, and dread, more especially deserves the name of *melancholia*. A vast variety of ideas, whether true or false, may give rise to these emotions. Thus the monomaniac believes himself to be ruined, abandoned by his family, and betrayed by his friends; sometimes he fancies himself surrounded by spies, enemies, and assassins, or that he is subjected to the malign influence of evil spirits, or under the spell of witchcraft, or suffering from the deleterious effects of electrical and chemical agents, or of animal magnetism; others, conscious of the diseased state of their minds, imagine they will never recover, and despairingly regret being a burden to their families, and useless members of society. Oc-

asionally those circumstances which produced the insanity continue to weigh down the mind of the sufferer. One remembers that he has really been ruined, abandoned, and betrayed; another that he has been crushed in contending with powerful enemies, and that "might has overcome right." An habitual state of dread and fear is called *panophobia*; and *misanthropy* is that deep-rooted hatred and aversion, which some lunatics entertain towards their fellow-creatures. These are generally gloomy, solitary, suspicious, and reserved; their general appearance and expression of physiognomy, bear the impression of anxiety, fear, and timidity.

8th. With some the disease is characterised by excessive avarice, or the most unbridled passion of profuse expense, from the idea of possessing immense wealth.

9th. Hallucinations sometimes predominate; these lunatics imagine they hear voices, which continually follow and torment them, that they see the individuals who persecute them, or the evil spirits which haunt them, and are afflicted by other such like mental illusions.

10th. In other cases of monomania, the madness dwells on some particular condition of the body. Thus some monomaniacs imagine they have under their skin, in the throat, the stomach, the thorax, or some other part of the body, devils, enemies, animals, or poison, because, perhaps, they really suffer pain or experience an unusual sensation in those parts; others fancy their blood is tainted, that some disease preys on their vitals, and conducts them slowly to the tomb, that their body is without a soul on the vital principle, that their head is twisted the wrong way, that they are disfigured or metamorphosed into an individual of different sex, or into a wolf, dog, bird, or any other animal, that they are deformed and hump-backed, that their legs are no longer able to carry the weight of their bodies, that they are changed into a teapot, or made of glass, and are therefore afraid of being broken, and many other such fancies too numerous to mention.

11th. Monomania is often marked by a morbid excitement or exaltation of certain talents, which occupy their waking and sleeping thoughts; thus some are continually employed in endeavouring to discover the perpetual motion; others are constantly composing verses or making calculations, or practising music, or writing metaphysical dissertations, or other literary labours and mental lucubrations.

Mania is general insanity, or, at least, there is no permanent and strongly marked passion or predominant set of ideas. Some writers divide it into three varieties, which perhaps are merely different degrees of the same diseased state of the mind.

1st. With some maniacs the mind is continually on the stretch, and highly excited, exactly similar to what takes place in inipient intoxication, as when a person has

taken a dose of laudanum or an extra glass of wine. These talk and chatter a great deal, frequently expressing themselves upon every subject with surprising volubility and occasionally with much judgment and sagacity. This morbid activity of the mind prevents them from remaining long in the same place, or assiduously applying themselves to any occupation; they are great babblers, thoughtless, careless, and mistaken in their views, and cannot for any length of time be trusted to themselves, or allowed to indulge all their whims. On meeting with the smallest resistance they grow angry, and frequently work themselves into a state of frenzy, that at last it becomes necessary to place them under confinement. Then they believe themselves to be persecuted, and entertain the greatest hatred towards those by whose influence they were confined.

2nd. With others, who are of a quiet disposition, we perceive a mixture of reason and insanity, so that they may be said to have a method in their madness; their mind, if left to itself, would fall into the most complete derangement, into endless aberrations of judgment, confounding causes with effects, and drawing false conclusions; if, on the other hand, their attention is engaged by interesting objects, as conversation, reading, or writing, they frequently, for the time being, recover their reason and intellectual capacity.

3rd. The most intense degree of mania is that where the ideas are rapid, confused, and expressed with nervous agitation, shouting, singing, menaces, and other ungovernable and tumultuous emotions of the mind, during which they are scarcely sensible of external objects, their sense of consciousness is obtuse, and their intellectual capacity confined to narrow limits; the power of recollecting the past is very inert, and the memory of the present equally feeble. The passions and affections are evanescent and sometimes altogether dormant. It is often impossible to engage their attention, and even when engaged one rarely obtains a correct answer to the questions put to them; sometimes, however, they will enter into a long train of reasoning, and hold a connected discourse, but at all times with ideas originally false. Sometimes these maniacs are mischievous, furious, striking, breaking, and destroying every thing within reach. Often they are most disgustingly filthy in their persons and habits. When cured they generally have at least an indistinct remembrance of every thing which occurred, or which they had seen, heard, thought, willed, and executed during the continuance of the disease.

4th. Dementia, or fatuity, this is either primitive or secondary; in the latter case it succeeds to mania, or monomania; it may be considered the natural termination of these diseases, when not cured, and when the patients live a sufficient length of time for such a termination to take place. Dementia is often primitive when it accompanies decrepitude of

advanced old age, whether with or without organic affections of the brain. It is also common to epilepsy, drunkenness, excess of venery, and masturbation. Also with individuals who have experienced inflammations, or other severe diseases of the brain. The principal characters of dementia are the obliteration, or loss, of the memory of present impressions, whilst the remembrance of past events is often preserved with all the freshness of a recent occurrence, a want of connexion and association amongst the ideas, or train of reasoning, and a perfect indifference to all things present or to come. These patients are generally quiet and contented, occupying themselves but little, frequently talk to themselves, uttering unconnected words or broken sentences, and laugh or weep without reason: in a more advanced stage they are in a state of complete stupidity, having only a few detached or isolated sensations, yet, before arriving at the last stage of mental imbecility, there are fleeting moments of excitement, during which they grow angry, or become violent, and break or destroy, and are able to connect their ideas to reason, and sometimes to write letters not altogether destitute of sense. Notwithstanding the intellectual faculties are in a state of extreme torpidity, or decay, they are able to recognise their friends, to play very well at billiards and other games of calculation, and to satisfy the wants of nature. Women are able to pursue their accustomed occupation of needle-work, or such like; the talent of music, or drawing, continues in a high degree of perfection in the midst of the general wreck and annihilation of the other faculties. In this species of derangement much of the time is passed in sleep; the physiognomy loses its expression, and the voluntary movements become at length very weak, and the muscles paralysed; these also grow very filthy. Occasionally dementia is so slight as to be scarcely perceptible, but, in these cases, if they are required to write it is perceived they often forget entire words and letters in spelling, and that the style is no longer such as it was wont to be.

Some maniacs are in a state of continued stupor, they seem to be without wants, without ideas, and without desires; their eyes are open without seeing or observing; they neither listen nor yet speak; their skin is but little sensible; they would remain during the night as well as during the day in the open air, if they were not led to their apartment, to their meals, to the fire, and to their beds. When cured some say that they were almost deprived of the faculties of thought, will, and sensation, and that their existence was mechanical, or that of an automaton; others that their ideas were in such a state of chaotic confusion as not to be able to arrest or dwell on any of them; others compare it to extreme debility of mind, or a sort of mental atrophy. Sometimes this acute state of dementia is only apparent, the patient living in a state of mental

absorption, without uttering a single word, either because he imagines that should he speak he would instantly die, another because he has received an order to be silent, and some from one motive and others from another.

Idiotism, or Fatuity.—According to Mons. Pinel, idiotism is the fourth species of mental alienation; he defines it a sort of stupidity, more or less strongly marked, consisting of a very limited number of ideas and a want of decision or nullity of character. This definition includes both those idiots whose intellectual faculties have never been developed, as well as those who have suffered a diminution of mental capacity or obliteration of their reasoning faculties subsequent to their development in after-life. M. Esquirol gives the name of idiotcy to that state of the mind wherein the intellectual faculties have never been developed, whilst the accidental loss of thought is more properly referred to dementia. This distinction is well founded, for these two affections are different in their origin, and each is marked by characters of its own.

An idiot is one, who, from his birth, is more or less completely deprived of understanding; he forms one of a very numerous family amongst the human race, for there is a great number of degrees and shades of difference in the interval between the standard of mediocrity, or common sense, and the entire absence both of understanding and of the functions of the external senses: thus some idiots have merely a vegetative existence, they seem unacquainted with every species of sensation, and feel neither hunger nor thirst, nor any sort of pain; they are insensible to the inclemency of the season, and heat and cold make no impression on them; when food is put into their mouth they swallow it; when they open their eyes it is without being sensible or perceiving the objects around them. M. Esquirol speaks of a little idiot, eleven years old, who was deaf, dumb, and blind, and found almost lifeless by the side of its mother, who had been dead several days. Some idiots manifest a few sensations; they know their food, take hold of it, and eat it; they behold objects and know how to avoid them; they turn round when they hear a noise; if pinched, they endeavour to withdraw their bodies from the pain, and, sometimes, when vexed or contradicted, they put themselves into a passion; but they know not how to make use of external objects; they are unable to put on their clothes when exposed to the cold; they remain without seeking to change their place, and only think of eating when food is set before them; the whole extent of their language, by which they communicate their ideas, consists of a few simple signs and sounds variously modulated. Some faint traces of intelligence are to be met with in those of a higher station; the attention of these is sometimes engaged by

the impressions made on their senses; they seem to look at certain objects with a mingled feeling of pleasure and curiosity, will go of their own accord to any food they see and carry it off; they recognise those who are in the habit of taking care of them; sometimes, by means of cries and signs, they point out the objects they want, and express the pleasure or pain they experience. Yet it is necessary to put on their clothes, to put them to bed, or to place them where it is desired they should remain; but they are incapable of satisfying their wants, and all that can be done in the way of language is to make them remember one or two words by continually repeating them under certain circumstances. After these idiots, we may rank those who can recognise the members of the family with whom they live, and to whom they show a degree of attachment, as can help to dress themselves, understand some questions, can fetch their food, and imperfectly articulate several words; yet they are incapable of any kind of work, pass the entire day in lying down, sitting, or strolling about.

The term imbecility has been given to that species of idiocy where the intellectual faculties are only developed to a certain point. Consequently *idiots* may be considered such as are more or less *completely* deprived of understanding; and those with whom there exists some connected ideas, a limited use of speech, a little memory, and a consequent degree of understanding, may be termed natural fools. These natural fools, like the idiots, may be divided into several classes, according to the development of their faculties; but it is unnecessary to enumerate them, or enter into such distinctions. Generally speaking, they are capable of being employed in such simple operations as require but little judgment, the extent of their language is confined to a small number of words badly pronounced, but they cannot be taught to read, or write, or learn any useful trade; they know the value of money, and how to make use of it; many are inclined to steal, and are very cunning, which causes them to be supposed having more understanding than what in point of fact they really possess. It is difficult to explain the remote causes of this disease; in some families there seems to be an unknown hereditary predisposition, and several of the same family are subject to it. This is exceedingly common in those countries where cretinism is of frequent occurrence. Heavy affliction and painful losses pressing upon the mind during pregnancy appear to be sometimes a cause of idiocy; injuries on the head of the infant during labour, blows and falls upon the head, terror, inflammation of the brain, convulsions, epilepsy, may each of them be followed by extinction of intellect, or fatuity; but, more frequently, we are at a loss to attribute this disease to any preceding cause.

That species of fatuity which is known by the name of cretinism, proceeds from a local

cause; thus the victims are common in the valley of the Rhone, which is scarcely more than a mile or two in breadth, and walled in on either side with lofty mountains abounding with glaciers, and covered with eternal snows. Those parts more remarkable for those unhappy beings, are in the neighbourhood of marshes caused by the overflowings of the Rhone, exposed to a south-west aspect, and completely sheltered from the north-east winds. Hence the reflected rays of the glowing sun, concentrated, as it were, into a focus on these unhealthy places, produce a dense and heated atmosphere, which, combined with the enervating influence of the south-west, seem to produce that injurious impression on the nervous system which gives rise to the disease; for it has been observed that if young children in whom there are indications of cretinism, are removed to a higher part of the mountains, they gradually recover from the disease, even though they happen to be the offspring of cretins, whilst the children of those living in elevated situations are never afflicted with the disease. From hence, also, we may conclude that cretinism is not, strictly speaking, an hereditary disease, although there may be a greater predisposition towards it in the offspring of those who are afflicted with it, than in those who are free from it.

The causes of mania are often as obscure as those of fatuity; frequently it is hereditary, arising from some taint in the constitution, or morbid condition in the nervous system of the parents, thus those who are afflicted with insanity, frequently give birth to children who become insane, especially should they be born after the disease has declared itself; also scrofula is a frequent cause of this predisposition; the children of habitual drunkards, as we have already observed, are often idiotic or insane, and there is every reason to believe that those labouring under nervous diseases, produced either by physical or by moral causes, as severe grief, or hysteria, or epilepsy, occasionally give rise to a similar predisposition. In addition to these are to be enumerated the various physical and moral causes which act powerfully on the nervous system, and thus affect the brain. But very frequently insanity declares itself without any such apparent predisposing cause. On examining the brains and skulls of those who have died insane, we occasionally meet with various organic lesions of those parts in idiocy or fatuity, and sometimes in insanity. The tables of the skulls, together with the diploë, are greatly thickened and hardened, of the solidity almost of ivory, this is particularly the case in idiocy, where the cranium is generally of unusually small dimensions, not exceeding those of an infant, and those parts of the brain, which phrenologists consider as the seats of the intellectual and moral faculties of the soul (which are situated in the front and sides of the head), appear not to have been developed; hence the foreheads of these individuals are singularly depressed

and narrow, which gives them that expression of vacuity, which stamps the character. Sometimes the substance of the brain is of a firmer consistence than usual, at others it is reduced to a soft pulpaceous mass, but more frequently no alteration whatever is visible in its consistence. Some authors have imagined they had discovered a peculiar configuration of the cranium in those afflicted with insanity, but our celebrated countryman, Willis, who had paid much attention to this part of the subject, observed that though sometimes there was some peculiarity, yet more frequently there was none whatever. Consequently, gentlemen, no reliance is to be placed on such distinctions, for the shape of the head and the texture of the brain offer no visible mark by which the disease may either be recognised or predicted.

It is not the province of my chair to enter upon the curative means to be employed in the treatment of these maladies, of course such means must be regulated by the history of the case, the pathognomic symptoms of the disease, and the moral and physical causes which gave rise to it.

I beg to observe that monomania, and some particular cases of fatuity, where only a single faculty is manifested, or a single faculty deranged, seem very much to favour the doctrines of phrenology, viz. that the mind contains a given number of primitive faculties, and that the different parts or convolutions of the brain are the seats and organs of these faculties, according to the intellectual, moral, and physical qualities of man; and whereby the mind manifests those several qualities. As the brain consists of two hemispheres, each corresponding with the other, so is there a double set of organs, and hence is it, according to these doctrines, that very considerable injuries may be sustained without the faculties of the mind being sensibly impaired, as a man may lose the sight of one eye and yet the perceptions of colour, form, and distance receive no diminution.

Reviews.

The Practice in the Liverpool Ophthalmic Infirmary, for the Year 1834, being the First Special Report. By HUGH NEILL, Surgeon to the Charity. Pp. 55. Longman, 1835.

THE author's first object in the publication of this Report is to show to the Governors the number and variety of cases which are relieved in the institution. In the preliminary observations we notice, that in Liverpool, as well as in London, individuals in circumstances capable of remunerating a practitioner will suffer the disgrace of receiving advice gratis sooner than part with their money. We are glad to find Mr. Neill had the boldness to refuse such relief. The system is a disgrace to any elee-

mosynary institution. But to the contents. In the year 1834, 1,768 cases were treated, thus affording to the author a very ample field of practice. After giving a table of the diseases admitted, he proceeds to remark on some of the most interesting cases and affections.

Amaurosis the author has found to arise frequently from what he terms "astringent vapours," a circumstance which, he remarks, has not, he believes, been before noticed. In one case he attributes the attack to the vapour of coal tar. The man's employ is "applying coal tar to the concave surface of the arches of canal bridges;" he is now blind. Many men, it would appear, in the same employ are similarly affected,—a case is referred to as arising from the fumes of sulphur. *Strychnine*, the author states, is the chief and best remedy; he bleeds, blisters, purges, or gives tonics according to circumstances.

One extract will suffice to show the character of Mr. Neill's Report. P. 30.

Ulcers of the Cornea.

"Ulcers of the cornea are seldom the consequence of pustules, if the surgeon be applied to in time. Ulcers generally occur in strumous habits. The hospital surgeon is usually applied to when there is intolerance of light and lachrymation: and when he examines the eye, he finds one or two large vessels, twisting and twining from the outer angle of the eye; they may come from any part, but usually from the outer angle. When they reach the edge of the cornea, they appear to raise themselves above the conjunctival surface, they hang and twist about the edge of the cornea for a time, and ultimately rush forward upon it. They generally stop as near the centre as possible, and begin to show a little soft pulp at their extremity; this is an absolute ramollissement of the exterior surface of the cornea. The surgeon should immediately destroy this substance by the application of the nitrate of silver pencil. If this is not done a permanent speck remains. The false texture should be immediately destroyed, and the slough separated, in the event of which the case will go on well. To apply the caustic with advantage requires some dexterity, the patients being usually young. The little one should be laid on the knee of an assistant, mother, or nurse, turn the head back into your own lap, separate the lids, then apply your pointed pencil steadily, quickly, and surely. Do it *well at once* and you save much after annoyance; for reasons, known both to you and the child, this operation cannot be done so well the second time, the 'young one begins to know you.' The after treatment should consist in frequent fomentations with poppy-head infusion, and then a weak solution of sulphate of zinc.

"While on this subject I must advert to what has frequently been impressed on my observation, from consultations during the last twelve months of my practice, viz. that the

use of *acetate of lead*, as a lotion, is bad. In several cases, treated afterwards by me, where this salt had been employed, by gentlemen previously in attendance, a white slough, very hard to be separated, was created. When the usually great irritation has subsided, I stimulate the granulating ulcer with one grain or two grain drops of the nitrate of silver. The only internal remedy, which I give, is the blue pill mixture, three grains of the mass should be given in mucilage every night or fortnight."

The following is interesting in a metaphysical as well as in a surgical view:—

"October, 1834. There is at present in the Ophthalmic Infirmary, under Mr. Neill's care, a case of very great interest. The patient is a little girl, who was *born blind*. About three years ago Mr. Neill operated on the right eye, the operation was successful, and she obtained sight; she was then in her eighth year. On Saturday last, the 4th instant, he operated on the left eye, in the Slater-street Institution, with a similar happy result.

"This little creature, born blind, and for eight years in darkness, is now in full possession of this most precious sense. She can distinguish colours and the smallest objects. The knowledge of distance, after the first operation, was for a long time imperfect. The first object, which was presented to the eye, was a halfpenny; for weeks afterwards every circular object, no matter how large, or what colour, was called a halfpenny.

"When blind her residence was in Dovecourt, School-lane; she was then familiar with 'every nook and corner' in the neighbourhood. When she obtained sight she often used to lose her way, sometimes even close to her own door; the instant this would occur she would shut her eyes, and feel round until some known object was touched, then with her eyes closed she would hurry home, guided by her accustomed sense of touch. She is a pretty intelligent child, and is a pattern of neatness."

The Report does credit to Mr. Neill;—we would recommend him to continue it annually. The profession may derive some information from the present.

The Dublin Journal of Medical and Chemical Sciences, January.

The succeeding are the inferences made from a careful and elaborate inquiry into the influence of salt on the animal system, and its existence in the fluids in certain proportions in health and disease. He reiterates the doctrine that an excessive use of salt predisposes to *scorbutic* and other affections.

Dr. Muteer on the Injurious Effects of Salt on the Animal System.

"From what has been stated we may draw the conclusion, that the ultimate effect of an excessive use of salt is a debilitated state of body. Hence the constant appearance of such symptoms as depression of spirits, languor, lassitude, and want of muscular strength. We

have particularised some others, occurring in cases of a scorbutic character, that have frequently fallen under our observation, and where the immediate action of salt upon particular organs was developed; in most cases, however, the effect produced may merely be a debilitated condition of the body. This in itself may not be of serious importance, but as it renders the subject more susceptible to epidemics, it may be the source of much suffering and mortality. In large towns fevers, dysentery, and cholera often exist to a great extent among the humbler classes, while the rest of the community are quite free from them. Bad air may predispose to such epidemics, want of proper clothing is still more likely, but the difference in the diet is that to which, by the universal consent of writers, the greatest effect is to be attributed."

Dr. Graves has published a lecture on the subject propounding similar views.

We have not at present space for the notice of a most instructive case, by Dr. Montgomery, of a fibrous tumour, arising from the posterior surface of the uterus, so large as to entirely obstruct delivery, and where the Cæsarean operation was performed, though unsuccessfully. On a future occasion we may lay it under our readers' notice.

Page 49. The next is a "*Case of Recovery from Suspended Animation*. By Dr. Macwhirter."—"I was called, at about half-past 11 P.M., to a lady, who had been several hours in labour. I found the *os tinæ* expanded to the extent of a crown-piece, the membranes pressed forward by every pain, and the presentation 'breech' pain recurring regularly and forcibly every four minutes. About a quarter before 1 the membranes gave way, the liquor amnii was discharged, and the labour, which was a first one, advanced slowly, until half-past 1, when the breech was born. Suspecting that resuscitation would be necessary, I desired the nurse to have warm water at hand. The body and head were long *in transitu*; the funis was round the neck twice, I disengaged it, but could feel no pulsation. I got my fingers into the mouth of the foetus, and succeeded in bringing it beyond the verge of the perineum, but it did not breathe. In about ten minutes, by management and the uterine action, the head was delivered, and along with it the placenta.

"The infant appeared *dead*, indeed it was thrice felt convulsed *in transitu*. The face was as white as paper, but there was some colour in the lips, still no pulsation of the heart could be felt.

"I placed the child, with the placenta attached, in a warm bath, gently inflating its lungs with my own breath in the usual way; rubbed brandy on the chest, abdomen, and head, spine, extremities, &c. As the funis, when cut, did not bleed, I therefore tied it. After immersion for about half an hour I took it out of the bath, dried and wrapped it in a warm flannel, and made the nurse carry it

near the fire. I then continued the gentle inflation from time to time, and the spirituous friction, to the extent of nearly two bottles of brandy and whiskey, occasionally slapping the bottom, when, at length, about forty or fifty minutes after birth, it gave a sob. This was indicative of existing life, and encouraged me to persevere. It continued to sob, or gasp, at intervals of a minute or two, and I now found that I could feel the heart beat.

"The above means were most perseveringly continued until the circulation and breathing very gradually increased. At the end of an hour and a half the child gave a whimper; the eyes opened; the lips became red; it breathed regularly; cried lustily. It lived and continues to live."

The Edinburgh Medical and Surgical Journal. No. CXXII.

The present number is enriched with numerous select communications from the Medico-Chirurgical Society of Edinburgh, and the present fasciculus is the second that has been published, the first having appeared in the last quarterly number. We shall not enumerate all the subjects that have been discussed in that Society, and which were thought worthy of publication, but shall notice those articles we believe to be the most interesting. In reviewing the contents of a contemporary Journal—its scientific productions—we approach the subject with considerable delicacy; for the character in the play said "Man is but man after all." Nevertheless, as we made a passing comment on our other cotemporaries, we may remark on the present, that in its style, and in the value, and in the variety of its matter, its editors need not blush when contrasting it with others.

The first short article is by Dr. John Reid, on Phlebolites, a collection of small rounded bodies, occurring, in the present case, in the veins of the ligamenta lata of the uterus: they have not been noticed before by English authors. Their presence is usually in the veins. Dr. Reid has seen five cases of them—thrice in the uterine veins, once in the vesical, and once both in the vesical and uterine. They varied in magnitude from a millet seed to that of a pea, and in number from two to more than a dozen. Their situation, we are told, is "loose, in dilatations of the veins, allowing sufficient space for the blood to pass between them and the coats of the vein." Their composition, according to Mr. Kemp, appears to consist of the same materials as bone, namely, phosphate and carbonate of lime with animal matter; they are found surrounded by fibrous matter. With respect to their mode of formation nothing is determined; whether it be the result, as the author says, of a vital or a chemical action is but conjectural. Further observations are undoubtedly desirable. In the depending veins only have they been found situated. Cloquet and Beclard have noticed

them, but have not arrived at more correct data on the subject than Dr. Reid.

Immediately succeeding the above article is a "Case of Rupture of the Tendon of the Biceps Flexor Cubiti," by Sir George Ballingall. It shall be extracted verbatim.

"Mr. D— was a healthy active man, about 50 years of age, well known to many members of this Society as an eminent chemist and druggist. While raising a heavy weight with the tips of the fingers of his right hand, he suddenly felt a snap, accompanied with a numb pain in the lower part of the arm, a little above the elbow. The weight instantly dropped from his hand, and he was conscious of an inability to use his arm as formerly. On endeavouring to take off his coat, within a few seconds after the accident, he had great difficulty in doing so, owing to the swelling which had already taken place in the arm. On examination, there was observed a large tumour about the middle of the arm, occupying the seat of the belly of the biceps muscle. This being considered by Mr. D. as arising from effusion he had a pretty tight bandage applied. He now felt scarcely any pain, and comparatively little inconvenience in the use of his arm. Next morning, on removing the bandage, and examining the arm carefully, Mr. D.'s son, a medical man, was of opinion that the tumour, which had now increased much, arose entirely from the retraction and swelling of the biceps itself. In this opinion he was confirmed by finding, that in the hollow which existed below the tumour there could be detected a body apparently the tendon of the biceps, which was loose at one extremity, and could be moved from one side to the other with great facility. Bandages were now applied, consisting of two pieces of leather accurately and tightly laced, one to the arm and the other to the fore-arm, with a strap passing from the lower to the upper piece of leather, for the purpose of keeping the arm in the bent position. Owing to the patient using his arm much the bandages were not accurately applied, and after ten or fourteen days they were thrown aside. The tendon has gradually contracted adhesions to the neighbouring parts; and although there is considerable swelling of the muscle, and some difference between the form of the two arms, yet the patient can use the arm tolerably well. It is not by any means so strong as formerly, and he cannot make any great exertion with it. He experiences difficulty; and some degree of pain or cramp, in attempting to raise a weight with the points of his fingers, and finds the power of pronation considerably impaired in the affected arm.

"The preceding history of this very rare accident was drawn up at my request by my friend Dr. Balfour. Having been in the country at the time Mr. D. sustained this injury, I had no opportunity of examining his arm until nearly a week afterwards, when I was led, as others had been, to conclude that the tendon of the biceps was undoubtedly rup-

tured, or perhaps rather torn from its attachments; for, although the tendon could not now be moved freely from one side to the other, yet, upon throwing the muscles of both arms into action by bending the fore-arm against a resistance, the tendon of the left biceps sprung out as it were, and became tense, while no such thing happened in the right arm,—the flexion of the fore-arm being apparently accomplished by the *brachiius internus*, the flexors of the carpus and fingers.

“On examining the arms a few days ago, at the distance of eight months from the accident, I find that there is a considerable difference in their figure, the belly or prominent part of the biceps in the right or injured arm being higher up, and somewhat different in shape from that of the left. Immediately below the junction of the fleshy with the tendinous part of the muscle there is a considerable thickness or swelling, apparently in the tendon; and when the muscle is thrown into action, the tendon of the injured arm is less prominent and distinct than that of the opposite side. Mr. D. still finds the strength of the right arm considerably impaired. He complains of some difficulty in pronating the hand, and more especially in alternately rotating the radius outwards and inwards, as he has occasion to do in the act of pouring any powdered substance out of a wide-mouthed bottle into the scales. This last-mentioned circumstance I am particularly induced to notice, because, from the actions usually assigned to the biceps, it might have been supposed that the act of supination, rather than that of pronation, would have been impaired.”

—

AN ESSAY ON THE USE OF THE
ALCOHOLIC EXTRACT OF THE ACO-
NITUM NAPELLUS, IN THE TREAT-
MENT OF ACUTE ARTICULAR RHEU-
MATISM.

BY DR. LOMBARD.

*Physician to the Civil and Military Hospital
at Geneva.*

THE medical properties of aconitum have appeared to me so remarkable, that for the last two years I have made it the object of my especial researches, the results of which I am desirous of communicating to you, as far as regards the treatment of acute articular rheumatism. The preparation of aconitum which I have employed is an alcoholic extract, made with great care. The common extract is frequently inert, either in consequence of the very large quantity of amidon and other vegetable matters which dilute the active principle, or because it is badly prepared. The expressed juice of the plant, after undergoing a slight boiling in order to coagulate the vegetable albumen, is evaporated in a marine bath, redissolved in alcohol, filtered, and again evaporated at a moderate temperature. According to this method, the volatile parts are not

lost, as in the ordinary preparation of extracts, and the active principle, which, according to the opinion of some chemists, appears to be destroyed by heat, has not undergone any injurious modification. The result has proved that these precautions have not been altogether useless, inasmuch as I have derived great advantage from the extract thus prepared, whilst a great number of authors have declared the extract of aconitum an inert preparation, from which no benefit can be obtained, although employed in very large doses. The alcoholic extract has produced very marked effects on the patients I have treated with it. All have been speedily cured, and without the super-vention of any bad symptoms, as the following cases will prove.

CASE I.—*Acute Rheumatism of the Right
Shoulder-joint, of a fortnight's duration,
cured in forty-eight hours by the Aconitum.*

—M. G., upwards of 50 years of age, generally enjoying good health, never having suffered from gout or rheumatism, was attacked with acute pain in the left wrist and right shoulder-joints; the integuments covering the wrist are red and tumefied, and the slightest pressure or motion increased the pain in the parts affected. This state continued for eight days, during which mercurial frictions and opiates were had recourse to. During the second week, the affection of the wrist was partly removed by large doses of tartarised antimony and blisters, but the pain of the shoulder remained quite as severe; it completely prevented his sleeping. Under these circumstances, I administered half a grain of the alcoholic extract three times a day.

The effects of the medicine were very evident even the first night; the patient slept better than he had done hitherto; he could move his arm more readily, and the pain was lessened. No other effects were produced.

The next day the pain was so much diminished that motion was scarcely at all inconvenient, and the patient determined to resume his occupation, an amanensis. Same prescription.

The third day after the administration of the aconitum, and the nineteenth after the commencement of the complaint, pressure on the shoulder did not cause any pain, and the motions of the right arm were nearly as free as those of the left.

This case is a remarkable instance of a cure being effected by the alcoholic extract of aconitum. We find a disease of a fortnight's duration, and which had resisted various modes of treatment, much diminished in the space of twenty-four hours, and removed in three days. We cannot explain this rapid cure, other than by the specific action of the aconitum on the disease of the joint, for no evacuation had taken place which could give rise to the idea of derivation; the patient had neither sweats, diarrhoea, nor vomiting, and did not appear to experience any other effect from the medicine

than its beneficial and curative action. The cure has not been less lasting than speedy, for, for the last five months, M. G.'s health has been excellent.

CASE II.—Articular Rheumatism of the Shoulder, of three weeks' duration, removed in forty-eight hours by the Aconitum.—Vittel, a woman fifty-two years of age, was admitted into the hospital on the 18th of December. She says that, many years ago, she had acute articular rheumatism, which obliged her to keep her bed for many months, and to walk for some time afterwards on crutches. From that time she has enjoyed good health, with the exception that for the last three weeks she has suffered from severe pain in the left shoulder-joint. Within the last two days the pain has become so severe as to prevent all motion of the arm. The articulation is extremely sensible to pressure anteriorly; the digestive apparatus is not out of order, nor is the circulation disturbed. Leeches applied to the seat of the pain, and opiates, afforded no relief; accordingly, the day after the patient's admission, I ordered a grain of the alcoholic extract of aconitum four times a-day.

Eight grains were accidentally administered, and, as no injurious consequences ensued, I ordered two grains every two hours. The pain did not diminish greatly, but motion became much more easy. The third day after its administration, the benefit received was so great that the pain might be considered as three-fourths less than it had been; motion was no longer inconvenient, so that the patient could dress herself, and there was no pain on pressure. Vittel considered herself cured, and was desirous of leaving the hospital, but she staid two days longer to be certain that the cure was complete.

In this case, as in the preceding, the administration of the aconitum was quickly followed by the removal of the disease. The pain caused by moving the arm was so intense as to induce the patient to scream; nevertheless, forty-eight hours were sufficient to remove it completely, and restore the arm to its natural condition. No injurious effects were produced by the administration of from 20 to 24 grains of the extract in the course of three days, with the exception, that at the end of that time diarrhoea coming on, no medicine was employed; but the cure remained perfect.

CASE III.—Acute Articular Rheumatism occupying successively different Articulations, speedily cured by the Aconitum.—Soulier, a tinman, 30 years of age, was admitted into the hospital with rheumatism of six days' duration. He states that this is his first attack; he was seized with acute pain in both ankles; two days afterwards the knees became affected and tumefied, and finally the hip-joints the day before his admission. The pain appears to be chiefly situated in the fibrous parts, and

it is increased under pressure. The symptoms are attended with fever and anorexia. He was ordered half a grain of the alcoholic extract, at first five, then six, times a-day.

At the end of forty-eight hours the symptoms were much improved; the pulse, which was at first 100, was reduced to 80; the anorexia had disappeared, and the pain had left the joints which were affected, but had attacked the great toes, which were red and tumefied. Let him continue.

The day after, the tenth of the complaint, the toes are free, but the hips are again rather painful. On the 11th the left wrist and some of the articulations of the hand became inflamed, the integuments being red and tense. The dose of the extract was gradually raised to six grains in the twenty-four hours. On the fourteenth day he was totally free from complaint, and had the perfect use of all his limbs.

This case will furnish us with many important remarks. In the first place, we see symptoms of fever, and general malaise removed in forty-eight hours; we find the pain and tumefaction occupying successively different joints, but not affecting any one longer than two days, owing to the use of the aconitum, which pursued the rheumatism wherever it showed itself, and did not allow time for disorganisation to take place in the tissues. The following case will illustrate still more the remarkable property of the aconitum in removing the rheumatism wherever it tends to show itself.

CASE IV.—Acute Rheumatism occupying different Articulations, and yielding in seven days to large doses of the Aconitum.—Marie P—, washerwoman, 31 years of age, was attacked, three years ago, while engaged in a heavy wash, with articular rheumatism, which kept her in bed for three months, and rendered her a cripple for a long period. Eight days ago, she was again occupied in a very heavy wash, when she was similarly affected. The chest and head, and afterwards the limbs, were successively the seat of acute pains, which were soon accompanied with fever, and obliged her to keep her bed.

I saw her the ninth day of the attack, when she had a pulse at 90, with a hot skin; the left knee tumefied, hot, and very painful on pressure or motion. Both the hip-joints were also the seat of severe pain. Notwithstanding the presence of the catamenia, I ordered half a grain of the aconitum every two hours, in order to relieve the intense agony under which she was labouring, and which completely deprived her of rest. She slept the first night after its administration, and the pain was much diminished; the hips were free, but the knees were still painful. Ordered a grain of aconitum every two hours. This night, as likewise the preceding, the patient perspired freely. The rheumatism left the knees and invaded the great toes, which became tumefied and

painful. A grain and a half of the extract every two hours.

Pain has nearly entirely ceased; the lower extremities are free, so that the patient can stand for a few seconds; the increased perspiration continues; the catamenia are still flowing. Continue.

The next day, the thirteenth after the attack, the left shoulder, elbow, wrist, and the articulations of the hand, are the seat of acute pain and considerable tumefaction, more especially the hand; nevertheless, she has slept a little during the night; the pulse, which was previously at 80, has risen to 96; appetite and digestion good; perspires very freely; the menses have nearly ceased. To have three grains of the extract every second hour.

The shoulder and elbow are nearly free from pain, but the wrist remains swelled and painful; the joints of the hand are much improved, but those of the thumb remain swelled, and are rather painful on pressure; appetite not so good; pulse 96; bowels not open since yesterday. Three grains of the extract every hour and a half.

The day after, all the joints are free, but motion of the wrist and feet is still rather difficult. The right shoulder has become rather painful. Six grains every two hours.

The patient became convalescent, but relapsed in consequence of an act of extreme imprudence; while in a state of perspiration she rose only half dressed, and walked out for a couple of hours. In a day or two she was suffering intense agony in all the joints of the right arm; the slightest motion made her scream, but there were not any symptoms of general irritation. She began again with six grains of the extract, which was soon increased to nine, every two hours, by these means the pain and tumefaction were gradually removed, leaving the large joints first, those of the phalanges remaining inflamed two or three days after the shoulder, &c., were free.

As in the preceding case, we observe here the pain yields in a few hours, and the rheumatism itself is removed in 36 or 48 hours, and while in the previous attack the patient was obliged to keep her bed for three months, she was able to leave it this time in eight days. When, by a serious act of imprudence, she caused a relapse, the aconitum again speedily removed the complaint. The administration of very large doses of the aconitum, from three to four and a half scruples in the day, has not produced any injurious effects, neither on the alimentary canal, nor on the nervous system, nor even on the catamenial secretion, which continued to flow, in spite of the pain and the remedies employed. But the chief symptom which appears to result from the use of the aconite, is the abundant and almost constant sweating, but this is not to be regarded as a symptom constantly produced by this therapeutic agent, as this is the only case in which I have observed it. In all the other cases a cure was effected without causing an increase of the perspira-

tion, and even in Marie P., the subject of the present case, symptoms of improvement were not invariably attended with perspiration, as I observed during the relapse. Another remark is, and it will be verified by the sixth case, the rapidity of the cure in the large joints as contrasted with the smaller ones; the former were relieved long before the latter, which continued for several days tumefied and painful on pressure.

CASE V.—*Acute Articular Rheumatism with considerable effusion into the Right Knee, speedily cured by the Aconitum.*—Joseph Bech, carpenter, 30 years old, was admitted into the hospital six days after the commencement of the complaint. He says that he has suffered successively from pain in the loins, the shoulders, and the right knee, this latter joint having been affected only three days; it is much increased in size, and presents evidences of fluctuation. The slightest motion causes acute pain; he cannot bear pressure on the left clavicle; pulse ranges from 96 to 100; skin constantly covered with sweat; tongue white; the other functions normal. He was ordered at first half a grain of the extract three times a day, then six, eight, and ten times in the twenty-four hours. In the course of three days the fever and perspiration completely disappeared, the pain in the knee was much diminished, and its size appeared to be rather less. The dose was increased to six and seven grains in the day, and, by the sixth day, the pain of the clavicle and knee had quite ceased, and progression was only impeded by the synovial effusion, which was not fully absorbed. The knee had, however, diminished nine lines in diameter since his admission. He continued to improve, with the exception that he had a slight tumefaction and pain in the left wrist, but which were soon removed. In the course of a fortnight, the weather proving wet, induced an attack of lumbago and some pain in the knee, for which he had vapour-baths, but without benefit, and recourse was again had to the aconite, in the dose of from twelve to eighteen grains in the day, and he was very soon relieved, so that the man himself demanded that the pills should be continued in preference to the vapour-baths, as they were far more efficacious.

The case of Joseph Bech is another example of acute articular rheumatism soon relieved by the use of the aconitum. Within two days after its administration, the pain and fever disappeared, the appetite improved, all the functions became healthy, and in less than a week that considerable effusion which had taken place into the knee-joint was diminished three-fourths, so that the patient, who previously could not move even in bed without great pain, was able to walk without any other impediment than the mechanical one offered by too much synovia. While in the preceding case abundant perspirations ap-

peared to result from the use of the aconite, in the present one it ceased during its use, and did not re-appear.

CASE VI.—*Acute Articular Rheumatism of the Wrist and Joints of the Right Hand cured by the Aconitum.*—Madame B—, 59 years old, washerwoman, was affected three years ago with sciatica, and treated successfully with blisters. Since then she has not suffered from rheumatism until lately, when all the joints of the right hand, and especially those of the thumb, became the seat of severe pain and œdematous tumefaction, accompanied with partial redness of the integument; the slightest pressure caused intense pain in all the parts affected; general health good, and no symptoms of fever present. She was ordered a grain of aconitum every two hours, which was afterwards increased to two, three, and four and a half grains every second hour.

The first and second pill produced nausea and vomiting, but those she took afterwards did not have any effect on the stomach or bowels. The other symptoms produced by the medicine were vertigo, giddiness, a great vivacity of impressions whenever the eyes were closed, and which the patient compared to the magic lantern. The local effects in diminishing the pain were very marked from the first day of its use, and at each increase in the dose, the patient experienced immediately its sedative effect. The tumefaction was not so easily removed as the pain, for when the treatment was finished, there remained very evident œdema of the dorsum manus, and around the small joints. While the patient was under my care, the disease attacked successively the wrist, elbow, and shoulder, but although these affections were more intense and to a greater extent than those of the phalanges, they yielded much more speedily, so that the joints first affected were the last cured. The sixth day after the commencement of the complaint, and the third of treatment, the thumb was free; by the tenth the joints of the medius and ring fingers were the only ones affected, and two days after the patient was able to go to her employment, having merely a little stiffness in the hand.

The case we have just read will furnish us with many interesting remarks; in the first place, we find the stomach, at first disordered by the aconite, become so accustomed to it as to be able to bear very large doses with impunity for a fortnight. Secondly, we can ascertain with more accuracy the symptoms caused by the aconite, such as numbness of the diseased arm, vertigo, disordered vision, and considerable vivacity, almost always accompanied with gay and pleasing ideas. Thirdly, the amelioration of the symptoms and the diminution of pain were not less striking in this case than in the preceding; from the first day the pain was lessened, and each time the dose was increased the suffering

was alleviated in proportion; this latter effect was so evident, that when the patient was taking three grains every two hours, she thought she was under the influence of a narcotic. Again, we have seen the large joints, namely, those of the wrist, elbow, and shoulder, more rapidly cured than those of the phalanges, although these latter were the first affected. The œdema which took place around the diseased joints followed the same course.

I might mention two or three cases more of acute articular rheumatism removed by the use of the alcoholic extract of aconitum, but I think those already given will be sufficient to point out the value of this remedy, especially when I add, that I have not met with a single case which has resisted this plan of treatment; and when I compare the results previously obtained from antiphlogistics, opiates, sudorifics, large doses of tartarised antimony, and derivatives, I do not hesitate to declare myself in favour of the alcoholic extract of aconitum.

The researches which I have made prove to me that it possesses specific powers against rheumatism affecting the joints. It does not appear to destroy the rheumatic poison, since we see joints become diseased while the patient is taking large doses of the aconite; not possessing any preservative or prophylactic properties, it appears to cure rheumatism by neutralising its morbid action wherever it tends to fix itself.

The action of aconitum on joints affected with acute rheumatism soon shows itself; the patients have often told me the pain has been lessened within an hour, but most commonly the sedative effect requires some hours to show itself; the antiphlogistic action which removes the inflammation and tumefaction, whether it be internal or external to the joint, takes place more slowly; from twelve to twenty-four hours is generally the time required to effect this improvement, nevertheless sometimes thirty-six or forty-eight pass ere it is effected. Again, in two cases we have seen the aconite act more rapidly on the larger than on the smaller joints. We have already observed that swelling of the wrist and elbow, coming on several days after those of the phalanges, were removed some time before them. The influence of the aconitum is not limited to the joints itself, but extends to the synovial membrane, and assists very much in causing absorption of those effusions which take place in almost every case of articular rheumatism. We have already seen considerable effusion into the knee-joint absorbed very rapidly during the use of the aconitum.

Stoerck, who was the first to give this medicine in rheumatism, thought it possessed sudorific properties, but the details which I have given serve to prove that this opinion is erroneous; in fact, out of eight or ten cases of acute articular rheumatism treated with the aconite, in only one instance was there in-

creased perspiration; in all the others a cure was effected without any sudorific action; and even in one case (case the 5th), the use of the extract arrested the perspiration which had existed for a fortnight.

The influence of the aconitum on the nervous system is very remarkable. As soon as the doses were increased, I have always observed a certain excitement of the encephalon, characterised by nocturnal visions, gaiety, and a great vivacity of impressions. The circulation of the brain has appeared to be so modified as to cause vertigo, giddiness, and flushing of the countenance, but in no case have I observed injurious effects from its use, although I have given it in the dose of a drachm and a half in the four and twenty hours.

The digestive functions have been but little affected by the use of this medicine. I have seen in the greater number of cases the appetite improve about the second or third day, and continue to improve while under treatment. Some have complained of foetid breath, with a whitish tongue, but the appetite was good, and these symptoms soon disappeared. Diarrhoea occurred in one case only (case 2nd), and then the medicine was omitted, but this was only after the complete removal of the rheumatic symptoms. Having passed the different functions in review, and ascertained that none are modified by the aconitum, we are obliged to conclude that this medicine is neither a derivative nor a sudorific, but is a specific against rheumatism; its action is exerted on the fibrous and tendinous parts surrounding the joints, as well as on the synovial membrane which lines it.

I have very little to say with regard to the dose or mode of administration; it did not appear to be necessary to conjoin anything with aconitum, which I have always given alone; it is nevertheless possible that its combination with opium, or some other therapeutic agent, will assist its action in certain cases. Not being guided by experience, I was obliged to begin with very small doses, such as a quarter or half a grain two or three times a day; now, however, that I have found it to be quite innocuous in very large doses, I recommend medical men to begin with half a grain every two hours, gradually rising to six or nine grains, repeated as often in the day. It is not absolutely necessary to carry it to that amount, the largest I have ever given; but if I may judge from the effects of that dose, it may be employed even in larger quantities.

Conclusions.—1st. The alcoholic extract of aconitum possesses specific powers against acute articular rheumatism.

2ndly. It very speedily removes the pain and tumefaction, and the synovial effusions in the joints affected with rheumatism.

3rdly. This medicine does not act as a derivative on the skin or intestinal canal.

4thly. When given in large doses, it stimu-

lates the encephalon, and appears to modify its circulation.

5thly. The alcoholic extract contains the active principle of the aconitum, at least, as far as regards its anti-rheumatic properties.

6thly. It may be administered in increasing doses from six grains to a drachm and a half of the alcoholic extract in the twenty-four hours.

THE

London Medical and Surgical Journal.

Saturday, January 31, 1835.

AN EXPOSURE OF DR. RYAN, OR THE MILESIAN HIPPOCRATES, IN ATTEMPTING TO INJURE THE REPUTATION OF DRs. GRAVES AND STOKES.

THE repeated attacks which Dr. Ryan has thought fit to level against us in his would-be Journal usurping the name of ours, we should pass over in pity or in silence, were he to confine his croaking to the purpose of merely annoying ourselves; but when, crawling out of his pond, he chooses to croak in the ears of our worthy correspondents and contributors, we cannot exercise towards him an equal degree of forbearance; and, although we may have greeted for a time his emulous swellings and frog-like contortions with undiminished laughter and well-deserved derision, even those writhings, when carried too far, call for a different treatment, and compel us to put forth our strength, and, wielding the cudgel of castigation, to drive the annoyance back into its muddy covert. We regret the necessity we are under to inflict such chastisement, and will perform the operation with that mercy and good temper which, although he may not merit, nevertheless becomes our own superiority.]

Our readers must be aware by this time, from the repeated explanations which have appeared in this Journal, of the facts which led to the Doctor's secession from us on the 15th August, 1834, and of his subsequently erecting the

standard of revolt, and publishing, with what success he best knows, his rival, or rather pseudo-Journal. Those facts, we trust, our readers will acknowledge, reflected no discredit on the Proprietors of this Journal, whatever they might on the retiring party. The former fulfilled to the letter their contract with the learned but discontented ex-Editor; and their liberality in this respect ought to be fully appreciated, when it is declared that, long before his voluntary resignation, such was their opinion of his abilities, that they considered him a person little calculated to give a proper tone and character to such a public Journal as this. Indeed, remonstrances having been addressed to him upon this subject, he tacitly admitted his lack of energy, by consenting to the admission of a co-Editor. Soon, however, after this, the Doctor, to the no small joy of all well-wishers to this Journal, took his leave of it, the Proprietors having to the last, with a charity by no means allied to a thirst for sordid gain, tolerated him in the performance of a duty to which he was incompetent.

On this event taking place, the Proprietors of this Journal advertised their subscribers and the public of it, in such terms as were candid and appropriate, (See No. 134, p. 119,) and certainly not calculated to raise the bile of even their ex-Editor. But how did Dr. Ryan act?—In an article inserted in a number of his *spurious* production, which with singular perversity of intellect he entitles his 134th, although every subscriber must have known it to be his *first*, he says, “that the subscribers will have some reason to complain of a fraud being practised on them, should they be induced to buy a Journal not edited by Dr. Ryan, nor supported by the eminent friends whose contributions he had been enjoy-

ing.” Now, we would ask the Doctor, where the fraud lies? In his insinuation, as conveyed in the above, that he enjoyed exclusively the support of the eminent friends attached to this Journal, and by implication that he could, and would withdraw their contributions from its pages, or in our advertisement of which he complains, and which was intended to guard the profession and the public against that spurious abortion which *did avise* under the Doctor’s auspices, destitute, as he knows well, of those contributions which had mainly given *eclat* to this Journal?

The mode in which the learned Theban fulfilled his boast of the exclusive assistance alluded to by him, gives, we opine, the most pertinent answer to our query; and for this, we refer our readers to an article on that subject in our 152nd number, p. 696. They will there find that, while the Doctor, disappointed in his *very fair* attempt to mulet us of the Lectures of Dr. Stokes, who, by the by, after well weighing the circumstances of the case, and the just claims of both parties, awarded to us the sole right to publish his lectures, and corrected them himself for that purpose—we say, while the Doctor, on account of this disappointment was at sea, his Palinurus overboard, and no compass at hand, he suddenly obtained the assistance—(God save the mark!)—of an *Unknown Friend* in his utmost need. This *rara avis*, whose love of justice, forsooth, at once gave him, as we shall presently see, second sight, and pinned him to the Doctor’s tail, the Doctor represents to have sent him (pitying, we suppose, his foundering state) an epistle garnished with high-flown compliments, and, what was still more to the Doctor’s palate, a copy, or *pretended* copy, of Dr. Stokes’s Lectures, taken “*verbatim, in short-hand.*” Now,

reader, mark, although the hand which this Fidas Achiates wrote was *short*, his sight was *long*, even so long as to enable him to descry, at the moment of taking the lecture *verbatim*, the corrections and alterations which were only made afterwards for our sole behoof by Dr. Stokes himself! These accordingly appeared in Dr. Ryan's mock Journal, as well as in our own; but, reader, mark again, *not until a week after the appearance of the lecture in ours!* The necromancy or jugglery by which this singular feat was accomplished, remains to be explained by the Doctor himself, or by his subtle, ferreting, but, somehow or other, *unknown friend*, in the bodily existence of which curious entity we are, however, most violently sceptical, seeing that, without the aid of any such *questionable shape*, nothing could be easier than for our ex-Editor and very worthy Theban to do, what in fact we believe he did, that is, to copy the lectures in question out of our Journal *seriatim*, we being always a week in advance of him. And, as a further corroborative proof that the said "Unknown" was merely a phantom begotten in the Doctor's dis-tempered caput, we may observe, that when we suspended the publication of Dr. Stokes's last lecture for a short period, in order to try its effect on our diminutive rival, *eodem puncto*, his invisible, and, no doubt, intangible, prompter vanished into thin air.

We now, for the second time, challenge Dr. Ryan to exhibit, in the garb of flesh and blood, his more than suspected co-adjutor. Circumstances make strongly against his having ever existed; and the time is now come when, if he walks this earth, he should, to save the Doctor's credit for veracity, make his appearance.

We come now to the last scene which our Theban has thought fit, in the ple-

nitude of his wisdom, to exhibit. This may be found in his latest number, and certainly a more pompous or ireful blast never sounded in the lists of journalism than that with which he sends us greeting. A more termagant scolding, even from the purlieus of Billingsgate, never assaulted human ear, than that with which he belabours Drs. Graves and Stokes, *once*, by his own confession, his "eminent friends and valuable contributors;" but now, *hèu quantum mutati ab illis!*

After an uneasy fling at the legitimacy of our Journal which provoked our risibility, and after observing that two letters have appeared in it alleged to be written by Dr. Graves and Dr. Stokes, of Dublin, he proceeds,—“In justice, however, to those gentlemen, we waited to see whether the letters would be disavowed, as we had some suspicion of their being fabricated.” *Fabricated!* Reader, observe that; *not sent to us through the medium of an unknown friend in Dublin by the Holyhead mail, but—fabricated.* Verily, the Doctor might easily have satisfied his punctilious, but considering his invisible friend, very natural suspicions on this point, by examining with his own eyes the said letters at our publisher's office. The Doctor is acquainted with the handwriting of the gentlemen in question, and the letters were ready for his or any other unbeliever's inspection.

He adds,—“We moreover found it difficult to believe that two gentlemen, supposed to be in the possession of their senses, could by any possibility have written such ineffable nonsense.” Nonsense! most sapient Doctor! Surely you are disposed to be facetious, albeit you lack the talent. Who, pray, wrote the following egregious nonsense?—“*If the part of the chest be dull on percussion when the patient is in the erect position, and clear when he lies down, it indicates*

effusion into the pleura." Stuff so paltry and ignorant, that, as Dr. Stokes observes in a passage in his last letter sent to us, which you take especial care not to quote, the veriest tyro could not read it without laughter. Who wrote this, we demand, but yourself, most sage and critical Doctor? Again,—*"A kernel got by accident into the lungs of a child; in the right lung no respiratory murmur could be heard, but percussion gave a clear sound, proving that the kernel lodged there!"* Were not these and similarly stupid passages compounded by you or your unknown and justice-loving friend, and then audaciously attributed to Dr. Stokes, as having been delivered by him in his lectures? and after this do you presume to talk of nonsense? Blush, Michael, blush; if such a mark of ingenuousness, perchance, lurk hidden beneath your skin, let it now mount into your cheeks, and tinge them even till they emulate the flame that eternally hovers on your brazen pate—but prate no more of nonsense!

The ex-Editor, however, with his usual candour—that is, when he is obliged—acknowledges at last the authenticity of the supposed fabricated letters, but at the same time begins, as he thinks, to demolish their contents; and, first, he fastens upon Dr. Graves's letter to us, dated Jan. 1, 1835, which we published, and which is probably in the memory of our readers. Dr. Graves therein most positively disclaims the lecture given in Dr. Ryan's "mock," of the 27th Dec. last, observing that "it was libellously bad, and never delivered by him." On this Dr. Ryan comments with his usual acumen; Proteus-like, twisting and turning, and by all means avoiding the straight-forward truth; but, since he needs *must* acknowledge it, he does so in the most laughable style imaginable;

and truly characteristic of himself. Here is the *morceau*:—He very coolly writes,—"So it appears that the Doctor never delivered the lecture alluded to, and has not this season discoursed on the topics therein treated;" but, as if instantly repenting of having told so much truth, he goes on, *pilis horrendis*,—"We answer, that he *did* deliver the substance of that lecture last session." Aye, aye, Michael, but last session and this session are two different things; improvement is always upon the march, and you had no business to hoodwink your slender affair of subscribers by representing that which had occurred as occurring, what had passed as being present. Talk of fraud after this!—What an arrant knave must he be who would persuade us that day is night or winter, summer! It was a wretched piece of humbug; and, however you may rave about liberality, &c., expressly calculated to render your breeches' pockets pregnant. And yet, for all this crookedness and meandering, you are prone to attack with unheard-of severity in others this very sort of blind side you possess yourself, and to elicit from an atom of falsehood a skyful of smoke. In charity we advise you, for the future, to keep a sharp look out of your tenement of glass, and not to throw stones.

Proceeding in his career, the Doctor kindles into eloquence, and, with great glee, roasts at the fire of his genius (query, scalp!) a sentence occurring at the conclusion of Dr. Graves's letter, but as the display is rather obscure, and we are not fond of foggy illustrations, we shall let it pass without further remark, and proceed to the conclusion of his diatribe against Dr. Graves. These, then, are his concluding words,—*"In our pages Dr. Graves's lectures could only serve as a 'sullen ground' for the splendid course*

of Dr. Fletcher, which needs no such foil to set it off." To this we need only answer, that what is much coveted, but out of reach, is commonly vituperated. The learned Doctor will no doubt call to mind on this occasion the fable of a certain—(don't be alarmed!)—reddish-coloured—not biped, but quadruped, eyeing unattainable grapes!

The reader must now prepare to hear another flourish of trumpets, which ushers in the Doctor's attack upon Dr. Stokes, who, equally with Dr. Graves, repudiates the patched-up and misbegotten brood of lectures our rubicund friend introduced, no doubt very adroitly and with the very best intentions, into his pseudo-pamphlet of miscellanies. Dr. Stokes, in his first letter to us, dated Dec. 31, 1834, observing on the lecture inserted in Dr. Ryan's mock of the 27th of the same month, and which Dr. Ryan put forth as one of Dr. Stokes's, and a continuation of those which had already appeared in our Journal, flatly denies its authenticity, and says,—“This lecture was never delivered by me, but is obviously composed by the Editor, with the assistance of a few unconnected notes of various lectures which were delivered long ago, and not in the Park-Street School, notes which have been taken by some singularly ignorant person.” The Doctor (Stokes) then goes on to state that the lecture, as published in Dr. Ryan's *pseudo-Medical and Surgical Journal*, is such a tissue of absurdities and errors, that it seemed strange how any editor of a medical journal could be so blind to his own interests as to publish such a farrago. Let us see what Dr. Ryan says to *this very gentle* reproof. In the first place, he denies having perpetrated the clumsy fabrication, and, egotistically enough, assures us, that, were he to attempt such

a lecture, he could, *toto cælo*, outdo Dr. Stokes. So much for empty boasting; but the question arises,—Who *did* manufacture this medley lecture? and to this question Dr. Stokes has an undoubted right to have an explicit answer from our puny rival, inasmuch as his character as an individual and his credit as a teacher might suffer by having such a lump of “ineffable nonsense”—we quote Dr. Ryan's words on another occasion—fathomed on him.

Our Theban now proceeds to descant upon his reasons for publishing the murdered lectures misrepresented as being those of Dr. Stokes, and, after cudgelling his brains for every ugly epithet brooding there, and flinging them hot and hot at Dr. Stokes, he thrusts out one cloven foot at least, if not a pair of them, and accuses Dr. Stokes of dishonourable conduct in not giving to *him* what was the due of others! making his chagrin at the disappointment an excuse for his own indelicacy and want of good manners.

Our doughty ex-Editor now lights upon what he chooses to call an exquisite piece of philology, occurring in the commencement of a second letter of Dr. Stokes's to us; but, before we mount our Theban astride on his Pegasus, it may be as well to acquaint the reader, that, farther than the commencement of the said letter, our ex-Editor and critic would not go—gall and wormwood in the shape of indignant truths met his eye throughout this letter, the initiatory sentence of which alone he dared to insert in his petty miscellany, well knowing that, had he quoted more, some damning proofs would have appeared against himself; but we refer our readers to our 153rd number for an accurate copy of it. In the meantime, our Doctor is astraddle of his philologic Pegasus, capering away,

and flourishing in the ludicrous attitude of a Milesian hedge schoolmaster; and, first, he earnestly inquires whether Dublin contains a preparatory school for young gentlemen, doubtless hoping, should such be the case, to be dubbed philological master of the same. We heartily wish him success in his new speculation, feeling well assured that his talents are better adapted to such employment than to editing his miserable pseudo.—So on, Michael, on!

But let us examine the volley with which, like Sancho Panza on Clavileno, he departs: it consists of a confession of sorrow for having inflicted wrong in holding up his quondam “eminent friend and valuable contributor, Dr. Stokes, to the contempt of the profession.” Poor man! with what complacency he seems to think that he possesses the power to do all this. No idea enters his cranium, that his endeavours in that direction have been either abortive, or have recoiled against himself. He assumes to have shown that the testimony of Dr. Stokes against his unknown-friend-begotten lectures is unworthy of credit. But how does our medical pedagogue set about the matter?—Why merely by blazing forth a string of assertions not worth the breath which utters, or the ink and paper that record them, and which, bearing in our recollection his unknown, second-sighted (perchance cloven-footed), help-mate, we cannot help most cordially disbelieving.

To the lovers of a grandiloquent though impotent finale, we beg to recommend the following splendid piece of insane raving, which we carve for their delectation, from the Doctor's concluding *brutum fulmen*:—“If the Doctor (Stokes) will now be quiet, we shall not repeat our castigation” (very lenient, that); “but if

he won't, he must not henceforth expect to be treated with gravity.” “He” (alas; poor Doctor!) “shall be hunted” (God save us!) “through successive numbers” (why not generations?) “with pungent gibes and most unsavory similes” (mark the alliteration!), “made the special object of our bitter facetiousness” (a bitter clever fellow!), “and tossed” (not in a blanket) “by tempests of laughter from one end of the kingdom to the other!!!” Of what does this awful pepper of words savour, think you, gentle reader; is it of bombast, or stark staring madness?

We turn with disgust from this picture of malevolence and vile intentions, at which, however, we know not a few who laugh most heartily, and praise the Doctor for the mouthiness of his explosion. To them, in their mirth, we now say that the poor Theban's bewildered brain has given birth to tirades more magnificent in their structure, more exquisite in their polish, than the foregoing; for instance, we find in the concluding paragraph of Dr. Stokes's last letter to us, that he (Dr. S.), possesses an epistle of Dr. Ryan's, in which he (Dr. R.) declares his determination to be “*aut Cæsar aut nullus* among journalists.” We, however, can scarcely credit that our *ci-devant* Editor has the bump of conceit so strongly developed as to induce him to believe there is any resemblance, physical or moral, between the great Roman and himself. We would bet a giant to a pigmy, that every school boy knows the mighty Cæsar had a pericranium as bald as the palm of a lady's hand, but our Doctor sports a fine, bushy, flame-coloured top-knot. Cæsar, it is said, once made an outcry for help when in danger of drowning; but who ever heard or read, that on dry land, and in perfect safety, he stood bellowing at every turn because he was

detected in a wily attempt at deception? No, no, there is no resemblance, unless it be that both the Roman hero and our Milesian Hippocrates have passed beyond a certain Rubicon. Unfortunately for the latter, *his* Rubicon is by far the less reputable of the two, since he has overleaped the limits of consistency and good breeding. If he be not Cæsar, then, who is he? The answer is plain,—he is *nullus*.

Ambition that over-vaults itself, and ill-temper, will be the Doctor's undoing; the former, by prompting him to aim at a degree of importance for which he is unqualified, and the latter, by urging him to avenge on others that failure in his attempts which is attributable to his own deficiency. Dame Nature has confined his ability, for wise purposes, within a circle which his presumption, deeming too narrow, would fain overleap; but mental elasticity is wanting, and the achievement must remain unaccomplished, at least during the term of his natural life; what sort of leap may afterwards take place, and to where, we shall not attempt to explore, but end this, our first flagellation, with a sincere wish that he may not provoke another and sounder exercise of our editorial club, the thin end of which only, we assure him, has now in mercy been applied for his behoof. If our prayers be heard, he will cull, as a certain respectable but long eared animal is wont to do, a savoury meal out of an unsavoury and prickly subject, and if his digestion be good, profit by the feast.

We would, finally, advise the Doctor to adopt in future for his motto, "*mens sana in corpore sano*," and when his wrath becomes restive and unmanageable, to recollect, that of us, the parent trunk, he is but a withered and lopped off branch, displaying, it is true, a little verdure from

the sap he still retains, but which, when it is evaporated, which it will quickly be, will leave him, we repeat it, a *withered branch*.

JOHN WILLIAMS'S LETTER IN THE
PSEUDO-JOURNAL.

The letter in Dr. Ryan's last *pseudo*, signed *John Williams*, on the "*Cholera at Portsmouth*," is equally worthy of the author and the Journal in which it appeared. We cannot express our opinion upon it in more apt phraseology than in the *elegant* language of the author. It is then, we thank him for teaching us the phrase, "*a contemptible piece of egotistical buffoonery*." We pity the simplicity and weakness of the writer. Efforts less vigorous, however, have raised men even more obscure than *himself* into notoriety. He has tried the experiment before. We recommend him to pursue the same path. It will lead him to *revenge*.—We have done with him for ever.

A LETTER, SIGNED "M. D.," ON DR. RYAN'S
BASE CONDUCT TOWARDS DR. GRAVES
AND DR. STOKES.

*To the Editors of the London Medical and
Surgical Journal.*

GENTLEMEN,—As Dr. Graves and Stokes are both of them absent some distance from this metropolis, as a medical practitioner I am anxious to say a few words in answer to the virulently abusive attack that Dr. Ryan, in his journal of the past week, has thought fit to direct against them. Anything more ungentlemanly, more entirely devoid of every particle of right and honourable feeling, the whole annals of journalism will, I think, scarcely produce, and it is with no small shame and mortification I see the members of the profession to which I belong, involved in such proceedings, and the names of such men as Dr. Graves and Dr. Stokes, eminent in their profession, and enjoying the respect, the confidence, and even the admiration of their cotemporaries, made vehicles for violent and intemperate language. It is, indeed, a subject of deep humiliation to me, as a member of the medical profession, to find one

amongst us, one, too, moving in the higher grade of the body, forgetting what is due to his own character, and the character of a physician, condescending to adopt towards any person, more especially towards his brethren, a tone and language such as that the article in question exhibits, in which disappointment and spite, malice and impotent revenge, contend for the mastery, and in which expressions are used, natural, indeed, to vulgar minds and weak intellects, but having nothing in common with the attributes of learning, or the feelings of a gentleman.

Dr. Graves and Dr. Stokes are dragged, by main force, by this man, into this controversy, where they may be bespattered with the mire of such a contention, but can gain neither honor nor profit; and I perfectly agree with Dr. Stokes, that if medical instructors are to be subject to such uncalled-for and unprovoked attacks as these, "some steps should be taken to put an end to such a grievance." Uncalled-for and unprovoked, I say, because the proximate cause of all this abuse on the part of Dr. Ryan is simply because these gentlemen choose to repudiate certain statements put by Dr. Ryan into their mouths, which, besides being untrue in point of fact, betrayed a most lamentable ignorance in point of science,—ignorance so great, that Dr. Ryan himself, in this very article, is obliged to confess, that what he published, as part of the lectures of these gentlemen, was nonsense. Yet, with this confession in his mouth, and, therefore, as we must presume, with a feeling, that what the Drs. (Graves and Stokes) did on this occasion, was unavoidable, and imperatively called for to save their reputations for medical science from the injury, Dr. Ryan did all his possible, to inflict, Dr. Ryan has the unblushing impudence—the hardened effrontery—to attempt to hold up these gentlemen to ridicule; an attempt which, but for its being utterly contemptible as coming from such a quarter, ought to be visited with the indignant reproof of every honest mind. Utterly contemptible it is, and but that one regrets to see a person, who styles himself a medical gentleman and a physician, so forgetting himself, one might be tempted to turn the ridicule on this Triton among minnows, and expose him to that unbounded laughter, that the very mention of "his pungent gibes, his bitter facetiousness," could not fail to generate. But I spare him this, and I spare him also the exposure of his mare's nest about Dr. Stokes's grammar, not indeed in mercy, but because my indignant feelings will not allow me to treat a subject like this with ridicule and levity. As a member of the medical profession, I am interested in upholding its respectability, which must suffer materially, unless conduct like that of Dr. Ryan's on this occasion shall meet with that censure from all sides which it so richly deserves, and I live in hopes that the medical profession, true to itself, and

true to that honour which I hope is dear to the majority of its professors, will mark in some becoming manner their opinion of this unworthy proceeding.

Your's obediently,
M. D.

Foreign Medicine.

SOCIÉTÉ DE MÉDECINE PRATIQUE.

Sitting, December 4th, 1834.

Miscarriage arising from a diseased state of the Placenta.

BY M. SERRURIES.

A LADY, 24 years of age, who had been married three years, was seized with violent abdominal pains, in consequence of which M. Serruries was called in. She had had no children, and though four months and a half had elapsed since the last appearance of the menstrual discharge, yet, similar delays having frequently taken place, she did not consider herself pregnant.

The size of the abdomen, and the evident contractions of the uterus, caused M. Serruries to suspect pregnancy. As he was about to make an examination, the pains greatly augmenting, a fetus of four months and its appendages were expelled from the uterus. It was a male fetus, and, from its livid colour, appeared to have been dead some days. There was a slight discharge of blood both before and after delivery. Only on the centre of the placenta were observed the granulations which indicate its insertion into the body of the uterus, occupying only the space of a five franc piece; the rest of its surface was smooth and polished, presenting at irregular intervals tubercles of various sizes; many, especially towards the centre, were in a state of suppuration; the others were about the size of filberts, presenting, both externally and internally, the character of pulmonary tubercles; their thickness was four or five lines.

The sequel of the accouchement was favourable, and the patient was able to resume her ordinary occupations on the fifth or sixth day. M. Serruries regarded the morbid state of the placenta as the cause of the miscarriage. Adhering to the uterus merely to a slight extent, it only received fluids necessary to the relative life of the mother with respect to the child, in a proportion capable of sustaining it till the period of the miscarriage, but insufficient to prolong it to the final period of utero-gestation, the placental tissue also becoming less and less permeable from the successive development of tubercles which had already occupied the greater portion of this organ. This also explains why so little blood was lost.

A lymphatic constitution was common to the lady and her husband, as also a scrofulous predisposition.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, Jan. 22, 1835:—Joseph Nickson Haslam, Market Drayton; Webster Adams, Needham Market; Thos. Tattersall Roseow, Haslington, Lancashire; William Taylor Tyson, Canterbury; Thos. Theodore Campbell, London; Walter Monkhouse, Penrith; Henry Offrell Snowden, Ramsgate; William Archer, Sudbury; Francis Carbutt Fairbank, Sheffield.

MISCELLANY OF FACTS.

At the sale still proceeding of the extraordinary library of the late Mr. Heber, among the curious tracts sold was one entitled as follows:—"D. Gordon's Pharmacopœia, or a Table and Taxe of the Prices of all usual Medicaments, simple and composed, contained in D. Gordon's Apothecarie and Chymicall Shop, with M. Robert Farquhar's high Lodging, in New Aberdeen. Imprinted by Edward Raban, Aberdene, 1625." A note says that a copy of this work, which occupies very few leaves, "at the Gordonstoun sale brought 5*l.* 7*s.* 6*d.*" It now fetched only *four shillings!*

The Duke of Northumberland has presented fifty pounds in aid of the funds for forming a museum for the Medical and Surgical School of Newcastle-on-Tyne.

Deronport and Stonehouse Dispensary.—A meeting of the governors of this institution was held on Tuesday last, Lieut.-Gen. F. Somerville, R.N., in the Chair, to take into consideration the recommendation of the Committee, "that the vacancy occasioned by Dr. Black's resignation be not filled up, and that the duties be divided amongst the present medical officers." Between twenty and thirty of the governors were present. Mr. May proposed a resolution in the words of the recommendation of the Committee, which was seconded by Mr. J. Burrows. To this Mr. R. Rundle proposed an amendment, "that the vacancy be filled up, and that no alteration be made in the distribution of the duties." Some objection being made to the latter part of the amendment, it was withdrawn; and on the question, simply that the vacancy be filled up, being put, it was carried by a majority of seven to two, neither the mover nor seconder of the original proposition voting on the occasion. Several of the governors present did not vote; and the feeling was so general that an alteration in the distribution of the duties was desirable, that it was understood the subject should be freely discussed and decided upon at the next general meeting. According to the rules of the institution, the medical department consists of two physicians, six surgeons, two apothecaries, and a dispenser, who are considered permanent. By a recent regulation the number of surgeons has been increased to eight. The annual report, dated 24th Sept. 1834, gives the number of physician's patients admitted since the last report at 354, and the number of surgeon's patients at 159, being equal to 191 to each physician, and to only 18 to each surgeon.

Sheffield Medical School.—We regret to have to announce the destruction of this school by fire. A quarrel having arisen between the porter and his wife, she ran out crying "murder," stercs instantly arose about lurking, &c., the mob attacked the school, and the work of destruction went on furiously until the most serious damage was produced.

APPOINTMENTS.

Naval.—Mr. Chrichton, assistant-surgeon to the San Josef. Mr. Charles Mayberry, surgeon to the Portsmouth Ordinary. Mr. J. L. McCall, assistant-surgeon to the Pike schooner. Mr. Robert Denmark has been appointed an assistant-surgeon, and goes to Haslar Hospital. Mr. James Selick, assistant-surgeon, from the Victory, to Haslar Hospital. Mr. J. H. Martin, assistant-surgeon to the Curlew. Mr. W. Rey, assistant-surgeon to the Victory. Mr. W. Dunbar, assistant-surgeon

to the Speedy. Mr. J. Dunne, acting-surgeon of the Larne. Mr. John Hoste Martin, assistant-surgeon of the Larne. Messrs. C. L. Fuller, J. Gordon, and J. Robertson have been appointed surgeons.

Military.—Assistant-Surgeon Turner, of the Ordnance Medical Department, to the station at Island Bridge, near Dublin.

General.—Edw. Duke Moore, Esq., apothecary to the Queen's Household, in the place of Magnus W. Andrews, Esq., deceased. Mr. R. D. J. Evans, surgeon of the Hertford General Infirmary, in the place of Mr. T. R. Colbeck, resigned. Mr. Francis Sharpe, surgeon to the Leeds Lying In Hospital.

DEATHS.

Dr. G. Roberts, of Quebec, formerly of Belturbet, Ireland. Mr. James Lyde, surgeon, Glasgow. Mr. William Cooke, of Wolverhampton, surgeon. Mr. C. Bingham, of Lichfield, surgeon. Mr. Jas. Farnish, surgeon, of Sheffield, late of Cambridge. Dr. Thos. Naughton, of Rostellan, County Meath, aged 91. Mr. John Scudamore Lechmere Tateshall, surgeon, of Hereford. Dr. W. B. Millan, of Dundee. Mr. J. M. Bowman, surgeon and Mayor of Ripon. Mr. Thos. Janes, of Rockampton Lodge, Gloucestershire, surgeon. Mr. James Moffatt, of Hexham, surgeon.

BOOKS RECEIVED.

A Treatise on Rickets; with a new Theory of Ossification, and a plate and description of an improved reclining couch for the distorted. By J. HUME WEATHERHEAD, M.D., Lecturer on Materia Medica and Therapeutics at the Westminster School of Medicine, &c. pp. 123. Renshaw: 1835.

QUAIN'S Anatomical Plates. Fasciculi 21 and 22. Plates 41, 42, 43, and 44. The plates present in a very distinct manner the muscles of the back and neck, the most difficult parts of anatomical study. Students would be well repaid by the labour of examining them. They are correct.

Observations on the Cause and Treatment of Ulcerous Diseases of the Leg. By J. C. SHENDER, M.R.C.S.L. pp. 210. Longman: 1835.

CORRESPONDENTS.

We are much obliged to our correspondent T. H. for sending us the particulars of the paper read by Sir H. Hallford before the College of Physicians on Monday last. We have not room for our comments this week; in our next they shall appear.

The valuable Clinical Lectures of Dr. Roots will be commenced in our next.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

LECTURES

INTRODUCTORY TO THE COURSE OF THE
INSTITUTES OF MEDICINE,

DELIVERED BY

ROBERT J. GRAVES, M.D.,

King's Professor, Dublin.

LECTURE IX.

GENTLEMEN,—There can be no doubt that certain periodic quantities of time hold a very intimate connexion with the conditions of the human system, both in health and disease. Many diseases, particularly those of a febrile character, have been long remarked for the tendency they manifest to terminate by what is called a crisis on certain days, and many of the healthy functions of the system exhibit a more or less distinct periodicity, of which the appearance of the menses in females is perhaps one of the most remarkable instances. Accurate observation has established that none of the functions of the body is performed in a perfectly steady or equable manner. They are subject even to a diurnal periodicity; thus the pulse, and the consumption of oxygen by respiration, exhibit slight but notable variations, which have periods of twelve hours, and it is highly probable that the same law holds with regard to animal heat. The consumption of oxygen, the development of animal heat, and the digestive activity are all greater in winter and spring than in summer and autumn. Of all the periodic numbers, which have been noted by the professors of medicine in ancient or modern times, the number seven in point of days or years seems to be most intimately connected with the revolutions of the human system. At seven years the milk teeth are shed and a new and permanent set make their appearance; at fourteen those important changes in the physical and moral character, which constitute puberty, begin to manifest themselves; and at twenty-one the individual is supposed to have arrived at the years of discretion, or, in the common phrase, is said to be of age. From this up to the ninth septen-

nial period, the connexion of the number seven with the changes in our systems becomes less apparent, but I have no doubt but that a more accurate observation will show that influential modifications of the system, whether physical or moral, may be observed at each septennial period during this interval. Thus at eight-and-twenty a man is supposed to arrive at the full perfection of intellectual and bodily powers, at five-and-thirty the characters of manhood, mature, reflective, and provident of the future, become distinctly marked, and although, during the succeeding periods, the physical and moral revolutions are faintly shadowed out, and life appears like a stream, to the eye of a remote spectator, descending in a noiseless and unchecked current, still a closer inspection will show that its course is modified by certain appreciable changes, and that these changes are connected with climacteric periodicity. In this country females generally begin to menstruate about fourteen, and at forty-two this function is either interrupted or stops, and they cease to bear children. Among males, sixty-three has been long noticed as a period at which the constitution is very apt to break down, and hence it has been termed the grand climacteric. If you cast your eyes round the circle of your friends and acquaintances, you will find many persons, who have arrived at this age, beginning to manifest indications of declining health, losing flesh, and become weak, nervous, and dyspeptic without any obvious cause. This constitutional struggle goes on for months, the individual loses his strength and spirits, he becomes pale, emaciated, and valetudinary, and his friends remark that he is breaking up very fast. After a certain length of time matters come to a crisis, the constitutional debility and uneasy feelings terminate, either in some distinct and decided form of disease, or an unexpected and unaccountable change for the better occurs; the patient begins to recover his appetite and strength, good digestion, sound sleep, and a flow of spirits gradually return, and he is congratulated by his acquaintances as one who has dipt in the fabled fountains of youth and got a new lease of existence. He now goes on favourably until he arrives at that period,

which is considered to be the average duration of long lived persons, three score and ten.

Such are the changes which occur at the various septennial periods. They are more prominent at the commencement and termination than during the middle, but if we were in possession of more accurate knowledge on this subject, it is very probable that we should find that none of these periods passes without some form of constitutional disturbance. In youth the processes, which mark the progress of moral and physical development, give to these changes a more palpable character, and in old age, when the powers of the constitution are weakened, periodicity also exhibits itself in a more determinate way. Sir H. Hallford has written a very interesting memoir on this subject, and certainly his observations appear to be borne out by facts. You will frequently have occasion to notice the breaking up of the system, which occurs about the grand climacteric, and you will see some persons, after wrestling with it for a considerable time, sink under some well marked disease, while others will rally, regain their wonted vigour, and go about for years in the full enjoyment of health. I may mention, in addition to what I have said respecting the number seven, that it seems to hold a very extensive relation to the critical termination of fevers. We have, as almost every one knows, seven, fourteen, and twenty-one day fevers; and it has been long remarked, that critical terminations are very commonly observed to occur on the seventh day, or on some day the number of which is formed by one of the multiples of seven.

The decline of life is accompanied not only by a failing of the physical energies, but also by a decay of the intellectual powers; the brain shrinks, and its specific gravity becomes greater than in an adult of similar stature; its functions are now carried on with diminished intensity, and the intellectual lights become proportionately dimmed; memory fails, imagination is no longer vivid and exursive, the pleasures of sense lose their attraction, and the objects of human pursuit appear hollow and unsubstantial. Amidst this wreck of intellect, feeling, and health, the old man would be in a truly melancholy and cheerless state, had not nature provided against his total desolation in the survival of some important affections, the tendency of which is to reconcile him to himself and his species. One of these is the love of life, a selfish principle no doubt, but given to man for the wise purpose of counteracting that propensity to self-destruction, which irksomeness of life is apt to generate; the other is the love of offspring, which prevents the unnatural transfer of property, and connects the old with the young generation. The wisdom of making the affections of the aged take new root in their grand-children is sufficiently obvious; by this provision the extremes of life are brought into contact, and the leaf, though sear and withering, covers and protects for a time the bud yet too tender to bear exposure.

Many interesting considerations present themselves connected with the duration of human life. Three score and ten has been long reputed a good old age, being, as an old author remarks, a good medium, by which the world is neither overstocked nor kept too thin. It is not merely a selfish motive which makes us pursue these enquiries, for be assured that as we succeed in improving the rules of life, and as a knowledge of those agents, which tend to lengthen or shorten its duration, becomes more generally diffused, mankind will profit by the investigation, and the average duration of human existence will be extended. Much benefit has been already derived from such enquiries in all civilised countries. I do not fear contradiction when I assert, that the prolongation of human life is a decided advantage, because, in proportion as the judgment of the old is brought to act on the passions of the young, will the wisdom of nations accumulate, and the solidity of individual character be increased. In making an estimate of the physical qualities of the human race, longevity should form one of the ingredients, and it is a subject which deserves the notice of the politician and the moralist as well as the physiological inquirer. That nation, in which life endures longest, will, *cæteris paribus*, exhibit the greatest solidity of intellect. Where the duration of life is short there is more or less probability that the decisions of the state will be acted on by the passions and impulses of the young. There is a great difference between the average duration of human life in England, and in Italy, and the south of Europe, and this is perhaps a circumstance which, as long as it remains relatively so great, must tend to make the English a wiser and more solid people, and must render their laws and institutions more secure than if generation were to succeed generation with great rapidity.

With respect to the greatest duration of human life in later times, I believe the oldest well authenticated *modern* on record is Thomas Parre, who attained the extraordinary age of 152. It is said that "Old Jenkins" lived to the age of 169, but this has not been sufficiently ascertained. The celebrated Drakenberg of Norway, who died at the age of 147, remained a bachelor until his 111th year, when he came to the resolution of taking a wife, and was married with great pomp, his nuptials being attended by the whole Danish court. He continued to enjoy the blessings of the matrimonial state for several years, and what is rather uncommon survived his wife. If you turn to the article Longevity, in any of the Cyclopædias, you will find an account of the most remarkable instances of long lived persons, it is, therefore, unnecessary for me to detain you by accumulating examples. During the course of my practice, or in the circle of my acquaintance, I do not remember to have seen in this country any person above 105 or 106, but I have very recently conversed with

a very intelligent lady about that age. During the past week, as you may have seen in the newspapers, a person has died at the age of 114, and in different parts of Ireland individuals have been known to reach the age of 120.

It is a common opinion, not only at present, but has been some thousand years ago, that the human race is in a state of degeneration, that man from being a giant has dwindled into a dwarf, and that his bodily vigour has sustained a proportionate diminution. You will find this opinion frequently expressed in the writings of Homer, in which Nestor so often deploras that the colossal stature and enormous strength of the heroes he had known in youthful days can be no longer found. The same opinion was maintained during the historical era, and still exists to a very great extent. We hear men constantly complaining not only of the moral, but also of the physical, degeneracy of mankind, and the present race are said to be but pigmy types of their tall and athletic ancestors. I believe most of these assertions have but little foundation in truth, and that, in point of strength and stature, mankind has not diminished so much as the admirers of antiquity suppose, while in the matter of longevity they have considerably surpassed their predecessors. From historical records, and from an examination of the lists published by the Roman censors, in which the number of the citizens, male and female, with their respective ages, was given, it appears that the average duration of life among the Romans, when compared with the English of the present day, is as thirty to forty-five. Thus out of thirty Romans, as many would die in a given period as out of forty-five Englishmen. This is a great difference in mortality, and here, at least, we have proof that men were not so long lived eighteen hundred years ago as they are at present. Moreover, it has been established that the term of human life has not only increased since the time of the Romans, but that it has received a considerable addition even within the last hundred years. So great has been the increase in the mean duration of life, that the tables which were made sixty or seventy years ago, and which served as the basis of their calculations for insurance companies, have been found to have underrated the duration of life very considerably. The consequence of this error, however, has turned out very favourably to themselves, for as the rates of insurance were calculated and charged according to their limited estimate of the duration of life, their profits during the last fifty years have been enormous, owing to this cause, that out of a given number of persons taken seventy years ago the average number of deaths would considerably exceed what it would be at present. We have, therefore, full and satisfactory proofs that life has increased in a very remarkable manner throughout Great Britain within the

last century, not only among the rural population, but also among the inhabitants of towns and villages. In London, the duration of life is nearly twenty-five per cent. greater than it was in 1734. Now to what are we to attribute (and this is a most important question) this remarkable and satisfactory increase in the duration of human life? Partly (and I mention it with feelings of pleasure and pride) to the various important and valuable improvements in medicine and surgery. Many diseases at present treated with success, were at that period either managed on false and empirical principles, or they were looked upon as incurable and fatal. I need not recur to the time when fistula in ano and many other surgical diseases were deemed incurable, or refer to the long list of fatal complaints among lying-in women and infants, to the state of our science with respect to pulmonary and febrile diseases, or point to the improved treatment of syphilis and the blessings of vaccination. The progress of medicine, based on sounder and better principles, has been intimately connected with the diminution of mortality in modern times. Any one of these improvements in practical medicine would be sufficient to produce a diminution such as would be sensibly felt in the lists of mortality.

It would appear almost incredible what vast numbers of children were formerly lost, particularly in the ill-conducted institutions of former years. Among these, the Dublin Foundling Hospital is worthy of being recorded, to show the horrible consequences which result from gross mismanagement. I have read with feelings of sorrow and disgust the minutes published by a parliamentary committee on the state of this institution. It appears that during the space of twenty-one years ending in 1796, ten thousand two hundred and seventy-two sick children were sent to the infirmary; out of these forty-five recovered! Dr. Bisset Hawkins, who makes this statement, does not mention the cause of this frightful mortality, which earned for the physician the soubriquet of Herod the Great. The true reason of the mortality was, that to save trouble and expence these unfortunate infants were not provided with nurses, and that almost all of them were crowded into the venereal ward, where, by being spoonfed, they took the infection from each other. There was no nurse to give them the breast, and when they cried and became troublesome, they were dosed with laudanum to keep them still. And the laudanum did succeed in keeping them still, for many of them never awoke.

I would not cite this foul blot on medical practice, had it not been unparalleled in the history of the healing art; and did it not furnish a striking hint to the managers of public institutions, showing to what an appalling extent abuses may exist in such establishments. Indeed I will venture to assert, that the institution of foundling hospitals has

been on the whole productive of more harm than good. I pass over the circumstance of the child being deprived of the advantages of being suckled and attended by a mother, or a nurse interested in its welfare, and shall only observe, that in every institution of the kind, where helpless infants are congregated in great numbers, the greatest attention and care cannot prevent a mortality far beyond the usual average under different circumstances, and hence it is that foundling hospitals are now almost entirely given up, not from any motive of paltry economy, but from the necessary tendency they have to occasion a vast destruction of human life.

In England the rate of annual mortality has considerably diminished within the last seventy or eighty years. In 1780 it was calculated that one person out of forty died in the year; in 1790 only one in forty-five died, and, in 1821, the mortality became so low as one in fifty-eight. Here we have a cause capable of producing an amazing difference in the state of the population. With respect to the rest of the European states, the following is a comparative estimate of the rate of mortality:—one in twenty-eight in the Roman and Venetian states; one in thirty in Italy in general; one in thirty in Greece and Turkey; one in thirty-nine in the Netherlands, France, and Prussia; one in forty in Switzerland, Austria, Spain, and Portugal; one in forty-four in European Russia and Poland; one in forty-five in Germany, Denmark, and Sweden; one in forty-eight in Norway; one in fifty-three in Ireland; one in fifty-eight in England; one in fifty-nine in Scotland and Iceland; so that you perceive the duration of life in this country is very great when compared with others, and that whatever foreigners may say about our dull and foggy climate, it is a fact that we live much longer than those who dwell in the sunny climes of southern Europe. The boasted climate of Italy, with its soft vernal breezes and cloudless skies, gives a mortality of one in thirty, whereas among our Irish bogs it is only one in fifty-three, while in the Roman and Venetian states, more than twice as many out of a given number die as among the bleak districts of the Scotch Highlands. It is then perfectly well ascertained that in England, Ireland, and Scotland, the mortality is much lower than in the poetic "lands of the sun," Italy and Greece. But we are not to attribute the superiority of any country in this respect, either to its soil or climate, for there is no doubt that if civilisation, the blessings of a free government, and the enjoyment of the comforts of life were as extensively diffused among the Greeks and Italians, as they are among the inhabitants of the British Islands, the rate of longevity in these countries would be remarkably increased.

I have already alluded to the beneficial influence on human life which resulted from the numerous and important discoveries in medi-

cal science. The improved treatment of venereal, of puerperal, and infantile complaints, of fevers, pulmonary affections, and of surgical diseases too numerous to mention; all these have tended materially to prolong the duration of human life, but none of them can be put in competition with the truly great and invaluable discovery of Jenner. In order to give you some idea of the vast quantity of human lives saved by the introduction of vaccination, I shall call your attention to a brief statement of some facts bearing on this interesting question. In 1790, one out of every eight children born died of the small-pox; in 1820, only one out of 2066; that is, out of this number there are now saved about two hundred and fifty, who forty years ago would have died of small-pox. In 1779, the small-pox destroyed in Sweden 15,000 persons; in 1784, 12,000; in 1800, 13,000; in 1822, eleven.

It is an interesting but melancholy task to turn back for a moment to the history of past ages, and to pass in review the different causes whose fearful operation has at various times made whole countries desolate, and swept almost entire generations from the surface of the earth. As time will not permit me to enter upon the details connected with this subject, I must refer you to those historians who describe the state of England for two centuries after the departure of the Romans, as well as to the accounts given by contemporary authors of the depopulation by the sword, plagues, and hunger, which threatened to exterminate whole nations during those dark ages which followed the fall of the Roman Cæsars.

I have told you, gentlemen, that the average duration of human life has proceeded, *pari passu*, with civilisation and an improved state of living, and that men are generally much longer lived at present than they were during the middle ages. Yet some persons, more poetical than discriminating, believe that poverty and barbarism are the promoters of health, and that longevity is only to be found in the hut of the savage. The savage, it is true, displays great vigour and activity of body, and an astonishing endurance of hunger, fatigue, and pain; but it has been fully established, that the mean duration of life among them is far below that of civilised man; whole tribes of them are frequently swept off by epidemics, and the mortality among their children is enormous. Poets have taken a particular pleasure in singing the praises of him who derives food, clothing, and health, from the chase, who quenches his thirst in the cool spring, and makes his bed beneath the canopy of heaven, and they have given to poverty the reward of health, peace, and longevity; but unfortunately statistical inquiries have, by the dull reality of facts, destroyed all these beautiful illusions, and have stripped poverty of all its charms, by proving that the liability to

disease is increased and the duration of life diminished in proportion to the privations man is doomed to undergo. If you take thirty or forty persons in the middle class of life, and compare them with the poor of the Liberty in Dublin, or St. Giles's in London, you will find that the annual mortality among the latter is much greater, and that the term of life diminishes in proportion to the extent of their poverty.

It appears from a very interesting Essay, by M. Villermé, on the comparative mortality among the indigent and those in easy circumstances, both in the capital and in the departments of France, that there is a striking and remarkable difference. Throughout the departments, he states, the mortality is one in fifty among those who are in good circumstances, while among the poor it is one in twenty-four.

A similar difference, he states, exists between the mortality of the poorer and more opulent parishes of Paris. The density of the population, narrowness of the streets, and other local circumstances, generally supposed to be very influential on the public health, were proved to be very unimportant when compared with the single element, the general state of the people as to the possession or want of the comforts of life.

On an examination and classification of the deaths which take place annually in the Paris hospitals, it appeared, likewise, that the mortality is much less considerable among the tradesmen and artisans who generally earn a tolerable competence, than among those of the lower order who have no certain and constant means of support, and who are frequently exposed to a degree of penury which, while it tends, by weakening, to render the body more susceptible of disease, and less capable of resisting its attacks, serves likewise to undermine the moral energies, and give rise to mental sufferings which still further shake and debilitate the constitution. This latter fact proves that the resources of medicine are comparatively inefficacious when employed to cure disease complicated with the effects of previous poverty; and, on the whole, the evidence before us is strongly in favour of the conclusion, that the general diminution of mortality in France and England is chiefly owing to the ameliorated condition of the great mass of the people, and a more general diffusion of ease and comfort. Would that the same remarks were applicable to the country or to the city we inhabit!

Statistical documents are wanting to enable us to compare the mortality of Ireland or of Dublin with that of England or of London*, but I have no doubt the difference must be

striking. I draw this conclusion from personal observation, and from a comparison between the modern medical annals of the two countries. Whoever has witnessed the number of those applicants who crowd the doors of our medical Institutions, or has seen how inadequate the Dublin hospitals are for the accommodation of the sick poor,—whoever has followed the progress of those epidemics which almost annually devastate this city,—must acknowledge the extraordinary prevalence of disease in our metropolis. Need I adduce proofs of the squalid poverty and wretchedness of its victims? Shall I draw a sketch of what we every day see? The colours usually employed to depict human misery are too weak and feeble for the task; nor will the legislative or statistical inquirer, who endeavours to discover the true causes of all this wretchedness, derive consolation from the too-convincing proofs which everywhere abound—that ignorance, intemperance, and vice with all its varied features of deformity, have powerfully aided in producing this excess of human misery and degradation.

The frequent epidemic fevers which spread their ravages throughout the provinces of Ireland prove that its peasantry enjoy scarcely more immunity from disease than the poorer inhabitants of the towns. One fact is well worthy of notice;—these epidemics are usually preceded and accompanied by circumstances tending to aggravate the usual state of misery and want. Thus, when fever devastated a large portion of Ireland in 1822, I had an opportunity of proving that the distressed invariably became also the diseased districts—the invasion of typhus was always preceded by the march of dearth—the steps of pestilence but deepened the foot-marks of famine!

To explain the origin of that poverty which excites the sympathy of even strangers,—to account for a scarcity of provisions in a country whose ports are crowded with shipping employed in carrying away corn and cattle,—to investigate the sources of that pollution which has demoralised a people naturally open, frank, and generous, and has rendered excessive intemperance and improvidence the most venial parts of the national character,—belongs not to statistical medicine; the duty of the physician extends not to these subjects; his employment is to alleviate the effects without discussing the causes of misery and vice; but he owes it to society—he owes it to his country,—to proclaim aloud the existence of the evil.

* I have, however, given one in fifty-three as the annual mortality of Ireland, on the authority of Hawkins. How data were obtained to make this calculation is more than I can guess.

LECTURES

ON

MIDWIFERY & THE DISEASES
OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XVII.

*Mole Pregnancy—Signs of the Child's
Death—Classification of Labour.*

GENTLEMEN,—There is another singular deviation from the natural course of gestation, called *mole pregnancy*. From the very beginning of its development the ovum may be either so deficiently organised, or it may degenerate so completely, that its nucleus, the embryo, may either never have existed, or have been obliterated shortly after its formation. "Should the embryo die (suppose the first or second month) some days before the ovum is discharged, it will sometimes be entirely dissolved, so that when the secundines are delivered there is nothing else to be seen; in the first month the embryo is so small and tender that this dissolution will be performed in twelve hours, in the second month two, three, or four days will suffice for this purpose*." If the interval, between the death of the embryo and the expulsion of the membranes be at all considerable, they become remarkably altered in point of structure; as the embryo no longer exists, for the growth of which the venous radicles of the chorion had been so actively employed in absorbing nutritious matter, the supply of nourishment seems now to be directed to the chorion itself, which takes on a fleshy structure, and grows with considerable rapidity, being nourished by the vessels above-mentioned; such an ovum, which consists merely of the membranes altered in structure, is termed *mola*, *mole*, *false birth*, &c.

These morbid degenerations of the ovum have been distinguished according to the various appearances which they present; sometimes the ovum forms a cyst, containing water, blood, or air, or its parietes are converted into a spongy, fleshy, or tendinous mass, hence we have, among authors, the *mola aquosa*, *cruenta*, and *ventosa*, the *mola fungosa*, *carnosa*, and *tendinea*; sometimes we meet with a considerable chalky or calcareous deposit, *mola calcarea*, and in cases where moles have been retained a considerable time in the uterus, a more or less complete ossification of their substance has taken place, the *mola ossea*; these however are but rarely met with. Another species of mole is the *mola vesicularis*, or *hydatica*, which consists

of a mass of vesicles like hydatids, and which seem to be the absorbent extremities of the vessels of the chorion distended with serous fluid; this species of degeneration of the ovum frequently attains a very considerable size, equalling even that of a full grown foetus, whereas moles of the other species seldom attain a size larger than that of a two, three, or perhaps four months' ovum, and it rarely happens that the membranes of a three months' ovum have a degeneration of this sort.

The most common species of mole is the *mola fibrosa*, which is nothing more than a coagulum of blood, retained in the uterus after delivery, or severe floodings at any period of life, and squeezed by the pressure of the uterus into a compact form. In these cases the serum and red particles escape, leaving the fibrinous portion behind. This species of mole, although it may assume the appearance of pregnancy, is generally expelled spontaneously, and is seldom attended by dangerous results. In the preparation, which I here show you, the mass is simply a fibrinous cast of the uterine cavity. Among those which are upon the table you will observe that in many the embryo is disproportionately small, the short umbilical cord very thick, the parietes of the ovum thick, hard, fleshy, and lobulated; upon closer examination you will find that the decidua, which is of a natural structure, covers the external surface of the ovum, and that the amnion, on its internal surface, is likewise unchanged, the degeneration of structure is evidently confined to the chorion and placental half of the umbilical cord. In those preparations, where a section has been made, the chorion seems to consist of a fleshy fibrous structure, the arrangement of the fibres marking the lobuli which I alluded to; whether these be the remains of what would have been placental cotyledons or not is difficult to say. The symptoms denoting the existence of a mole are very uncertain, nor is any thing unusual to be detected for the first six or eight weeks; after this period the size of the abdomen is observed to increase with unusual rapidity, especially in the case of hydatic moles; this is accompanied with pain and frequently with hæmorrhages, which occur from time to time, in proportion to the degree of connexion between the mole and uterus, these weaken the patient considerably, inducing leucorrhœal discharge, œdema of the feet, with general indisposition and debility.

The expulsion of the mole itself generally clears up all doubts as to the nature of the case. Where it is of the hydatic species, the discharge of a few single cysts will frequently inform us of the nature of the complaint before the whole mass is expelled. A small quantity of limpid serous fluid suddenly discharged from the vagina without any previous warning, and ceasing as suddenly, is a symptom which will justify the suspicion of this species of mole being present. I need hardly say that this is produced by the rupture of some of the cysts,

* Smellie.

These cysts are supposed to be the bulbous absorbing extremities of the veins of the chorion distended with a serous fluid; but Bremser asserts that he has occasionally met with real hydatids among them.

The treatment of the patient during the expulsion of the mole will in nowise differ from that of abortion, and the same rules for practice in case of flooding, &c., in the one case will equally hold good in the other. The after-treatment of the patient will consist in a mild course of tonics, change of air, more especially to the sea-side, with the use of the warm or cold salt-water bath, shower-bath, &c., &c.

I now, gentlemen, come to the consideration of a subject of which I can truly say, that so far from approaching it with greater confidence the oftener I have to lecture upon it, the more experience I gain, the less and less satisfied do I feel with the knowledge which I have to impart to you upon it. *The signs of the child's death* before birth form a subject of diagnosis not less important than difficult, and must still remain imperfect so long as we are unable to remove the difficulties which surround it. "If there be any subject (says the admirable Mauriceau) connected with midwifery which demands the utmost care and attention of the accoucheur, it is the being able to determine whether the fœtus in utero be alive or not."

In cases where, from disproportion between the head and pelvis, from unusual undilatibility of the os uteri, tumours, or from any other cause which renders the passage of the head unusually difficult or dangerous for the mother, even with the aid of the forceps, it is of the utmost importance to be able to decide with certainty whether the child be still living, because if not, the perforation of the head may be performed, and the mother released from her danger and suffering.

On the Continent, especially in Germany, the Cæsarean operation is frequently performed in cases, not as in this country, *only* where the child cannot anyhow be born, but also where being known to be alive, it might, by diminishing the bulk of the head, be made to pass without danger to the mother. Here it becomes of immense importance to be able to decide with certainty whether it be still living, because, in cases under *these* circumstances threatening Cæsarean operation, if we are able to ascertain that the child is dead, the perforation may be performed, and the mother spared the danger of this terrible operation.

By enumerating the symptoms which have been considered to denote the death of the child, I should do but little in rendering this subject intelligible to you, for they are extremely equivocal and uncertain, and have frequently occurred when the result of the labour has not only shown the child to be alive, but healthy and vigorous.

To render this subject more intelligible to you, I shall divide the symptoms of the child's

death into those which occur *before*, and those which are chiefly observed *during*, labour. Of those which occur before labour I know but of one symptom on which we can rely with any degree of certainty—I mean the sensation of a weight or foreign body lying loosely in the abdomen. Whenever the patient rises from her chair, whenever she turns in bed, stoops, or in any way changes her position, she feels the rolling about of this weight. A woman may even dance when pregnant, and she feels no more of a living fœtus than she does of her own liver or spleen, but the moment the fœtus is dead it is quite different, the fœtus no longer obeys the laws of organic life, but those of gravity. I have, however, met with this symptom two or three times where the result of the labour has proved the child to be alive, and cannot exactly account for it. Without this symptom it is extremely difficult to determine whether the child be alive or not. A woman may affirm that she felt the motions of the child at the beginning of her labour, and yet she will bring forth a fœtus, which, from the degree of putridity, must evidently have been dead several days; another, just before her labour, feel very uneasy at not having felt the motions of the child for the last day or two; she is sure that it is dead, for she feels quite differently to what she did in her former pregnancies, and nothing can convince her to the contrary, yet, with all this, she is delivered of a healthy and vigorous child.

Among the symptoms which you will find usually enumerated as signs of the child's death are the following: The patient is seized with a sudden shivering of more or less duration, the bowels are disordered, she becomes pale, sallow, and of a dark leaden colour under the eyes; the breasts are flaccid; she loses her spirits and appetite; her breath is frequently foetid; and she complains of considerable languor and debility, and occasionally has a foetid slimy discharge from the vagina. With all this she feels no motion of the child, but has a strange sensation of cold at the lower part of the abdomen, which is diminished in size and remarkably flaccid. From these symptoms, taken altogether, we might conclude, with tolerable certainty, that the child has ceased to live; but there is not one of them which, of itself, can be considered as diagnostic; the stethoscope, also, does not afford us that assistance which has been supposed; the *souffle placentaire*, or sound of the uterine circulation, does not prove that the child is alive; the absence of the fetal pulsations is no evidence of its death: this you will understand from what I told you in a former lecture when speaking of the signs of pregnancy.

During labour there are many symptoms which, even when *separately* taken, will enable us to decide with considerable certainty that the child is dead.

In presentations of the head, a considerable swelling of the scalp is produced by the pressure of the os uteri and external passages, but

if the child be dead, there is no cranial swelling, and the scalp is felt flaccid and loose. This symptom requires, however, considerable qualification; where the head is small, the pelvis roomy, and the soft passages well dilated, it will present no swelling, and yet the child will be alive; on the other hand, if the labour be long and severe, a considerable swelling may have formed upon the head, and yet the child may have died some hours before birth. If the child has been dead some days, the scalp will not only be felt loose upon the cranial bones, but it will even become crepitous, from a degree of emphysema, the result of putrefaction. The bones of the head will frequently be quite loose under the scalp, producing a sensation to the finger, as Johnson very aptly terms it, of a bag of shells.

If the arm has fallen down into the vagina, as in cases of arm presentation, it swells very considerably, and becomes of a purple colour, in a living child, from the pressure of the os uteri and external passage; whereas if the child be dead, no swelling will be produced, and the epidermis will begin to separate. If the cord be prolapsed, the pulsation will, of course, immediately tell us that the child lives, whereas, if it be felt flaccid and empty, without pulsation, we may be as certain of the contrary. In presentations of the nates, the sphincter ani, in a living child, is always found contracted, and will distinctly contract upon the finger, and, in face presentations, the tongue will frequently be felt to move, but if the child be not alive, the sphincter ani will be found relaxed, flaccid, and insensible to the stimulus of the finger, and the tongue motionless and flabby. Besides these symptoms, the membranes generally rupture early, with scarcely any pain, discharging a highly foetid liquor amnii, more or less mixed with meconium. But you must be cautious, gentlemen, in not placing too much dependence upon the two last symptoms, for I have known cases where the stench has been so insupportable as to drive every body from the bed-side of the patient, where the liquor was of a dark brownish colour, thick, and slimy, and yet the child was born alive, and perfectly healthy; nor is the presence of the meconium a sure sign, because it frequently occurs in cases where the nates present. Nevertheless, in any case, *except* presentation of the nates or inferior extremities, the presence of the meconium will authorise suspicion of the child's death.

So much, gentlemen, for the symptoms which denote the death of the child; it will now be necessary for me to offer you a few observations on the *classification of labours*, and the *duration of utero-gestation*. I shall thus be able to commence the subject of premature expulsion of the foetus in my next lecture, and then proceed to the consideration of labour itself. It would be not less uninteresting than useless were I to enumerate the many different arrangements which authors have made use of in the classification of labours; for there are

few subjects in which their attempts have met with so little success.

Hippocrates divided labour into *natural* and *unnatural*, all those being natural in which the head presented; but, as I shall shortly prove to you, a presentation of the nates or inferior extremities is just as natural, nor is it scarcely possible to say what *is* and what *is not* a natural labour. Rœderer, Professor of Anatomy and Midwifery at Gottingen, has divided them into *natural* and *artificial*; this last division is subdivided into *manual* and *instrumental*, and these again into *forceps*, *lever*, and *perforation cases*, &c.; but this is far from being practical, we should never think of classing a bad compound fracture of the leg or thigh with a case of white swelling, merely because they happened to be amputation cases.

Modern accoucheurs have divided labours into *regular* and *irregular*, the regular consisting of all labours which may be completed by the natural means without danger; but the variety of labours is infinite, no two labours are precisely alike, and that species of labour which in one case may prove easy, in another may prove difficult or even dangerous. Dr. Smellie divided labours into three classes, viz. *natural*, *laborious*, and *preternatural*. Dr. Denman, again, has made four classes, viz. *natural*, *difficult*, *preternatural*, and *anomalous*. But this arrangement is liable to many objections; a labour may be very difficult, and yet perfectly natural.

The most comprehensive and simple division which I know of is into *eutocea* and *dystoceæ*, the one being healthy, natural, or favourable labour, the other faulty, defective, or unfavourable. It may seem rather pedantic to you to use Greek words, but I really know of no two words in English which will express this meaning correctly, and I am the more disposed to use them, because they are now in general use both in France and Germany; *δυσ*, as I have before told you, when prefixed to a word, does not signify mere difficulty, it denotes something which is faulty or unfavourable, *aliquid in malam partem*, as in *dyspepsia*, &c.

The *duration of pregnancy* in the human race is forty weeks, or two hundred and eighty days, and, as far as I know, it *never* exceeds this term. From the great difficulty of determining the precise moment when conception has taken place, it has frequently been supposed that women may exceed the term of utero-gestation, and numberless cases are on record to prove it; but they must be all looked upon with a very suspicious eye, for not uncommonly they are a vile attempt at imposition to conceal loss of character and honour; nevertheless, in the majority of cases women have no other data to go by than the last appearance of the menses, and it is nearly impossible, to calculate by these means only, up to a day with any degree of certainty. From this reason the Code Napoleon allows three hundred days as the extreme duration

of human pregnancy, or twenty days beyond the usual time.

In Great Britain and Prussia the law fixes the extreme duration at three hundred and one days, thus allowing three weeks beyond the usual time. But why should the human female alone have no definite limits to the duration of her pregnancy? do we see these extra long pregnancies in common life, where there is seldom or ever any object in having them? This was remarked so long ago as by Dionis. "A woman," says he, "goes nine months, if no extraordinary accident or disease causes an abortion; those who say they go a longer or a shorter time have often their own reasons." It is curious to see how well aware he was of the real nature of these over-term pregnancies, or *partus serotini*, as they have been called, and what shrewd advice he gives respecting the conduct of the practitioner on such occasions. "On some occasions," says he, "the surgeon must not maintain that women go constantly nine months, for if a new married woman at the end of seven brings forth as fine and lusty a child as if she had gone the full time, if a widow is delivered of a son who is to be heir to her husband, ten or eleven months after his decease, or if a woman is brought to bed eleven or twelve months after her husband has gone a voyage, shall we say that such things are impossible? The reputation and honour of these women are at stake, and therefore the surgeon, for the peace and credit of families, must not only pretend to be convinced of the possibility of them, but likewise bring parallel cases to illustrate and prove it." I do not quote this, gentlemen, that you should follow his advice, but simply to prove that the circumstance had attracted notice more than a century ago.

My excellent friend, Professor Naegele, whose profound knowledge of the subject is not less than his extensive experience, assured me that he had attentively examined every case on record, and had not found one in which he could place sufficient credit to induce him to consider the *partus serotinus* as possible. An exact register of every patient has been kept for several years at the Lying-In-Hospital of Heidelberg, the results of which fully confirm his opinion. Owing to the uncertainty of the data from which women generally reckon, he says that perhaps he might be inclined to allow fourteen days beyond the full term of utero-gestation, but no more.

It might be fairly asked,—What is it that induces the uterus to expel its contents always so punctually at a certain time after conception (viz. forty weeks), unless some accidental circumstance has occurred to excite it to a premature action? I would define the reason why labour usually terminates pregnancy at the fortieth week to be from the occurrence of a menstrual period at a time during pregnancy when the uterus, from its distension and weight of contents, is no longer able to bear that increase of irritability which accom-

panies these periods, without being excited to throw off the ovum.

At my next lecture, gentlemen, I shall commence the subject of *Premature Expulsion of the Fœtus*.

CLINICAL LECTURES

DELIVERED

BY DR. ROOTS,

At St. Thomas's Hospital.—Session 1834–35.

Intermittent Fever—Use of large Doses of Medicine.

GENTLEMEN,—In to-day's lecture, I intend to make some remarks on two or three cases of intermittent fever which have come under your observation during the present session.

The first case was that of James Rogers, a sailor, æt. 28, admitted into the hospital on the 2nd of October, and who, though he confessed that he had drunk hard, stated that he had enjoyed generally good health. Eleven months prior to his admission, while in China, he was attacked by ague, and the paroxysms had continued to recur until the time of his coming in, though the disease during that period had occasionally changed its type, being sometimes tertian, and regularly tertian, then changing to quotidian, then back again to tertian, and then again to quotidian. During these eleven months he had only been free from the paroxysms a fortnight, and of late the paroxysms have kept to the quotidian type, and the rigor was on him at the time of his admission.

His countenance had the sallowness peculiar to the disease; there was considerable emaciation, his appetite impaired, tongue white, bowels open, motions dark-coloured, pulse 60, rather feeble; complained of aching pains in the left shoulder and knee, and also of considerable pain, with sense of fulness, in the forehead and back part of the head. This latter symptom, though aggravated during the paroxysms, was, to a certain extent, constant. Before applying to St. Thomas's Hospital, he had been an out-patient for three weeks at another of our metropolitan hospitals, but was no better.

Having carefully examined the abdomen and chest, and being unable to detect either congestion or inflammation, or any disease of the viscera contained in those cavities, I directed him to be cupped behind the ears to ℥ij., and to take quinquæ sulphat. gr. v. 4tis horis with pil. hydr. gr. v. omni nocte, and to be put on milk diet.

The report of the next day states that the pain of the head had been relieved by the cupping, and that he had had no paroxysm. Bowels being confined, was ordered to take a powder of rhubarb and calomel, statim. Three days after, the report states that he had continued free from any paroxysm, that he had no pain of head, and felt much better; his

gums, however, were tender, and the blue pill was directed to be given only every other night. To continue the quinine.

The report of the 14th, twelve days from his first admission, states that his general health had much improved, there had been no return of ague, and that he only complained of some irritation about the anus from piles, for which some of the ungu. gallæ comp. was ordered. He was directed to take the quina every six hours only, and was put upon full diet.

On the 17th, the quina was reduced to once in eight hours; and, at the expiration of another week, he was discharged, perfectly well.

Now, you will observe, that in this case the disease had continued almost uninterruptedly for eleven months, and therefore that there was great probability that organic disease might have occurred during that period. The organs most prone to take on disease in intermittent fever are the spleen, the liver, the alimentary canal, the heart, the lungs, and the brain; but I was satisfied that the viscera, both of the abdominal and thoracic cavities, were free from disease, while the constant though not severe pain in the head convinced me that there was some congestion at least, if not inflammation, in the brain; therefore it was that I ordered the cupping, and you will observe that the vessels being thus unloaded the pain ceased. The next step then was to prevent, if possible, the recurrence of the paroxysm, lest, during the cold stage, the vessels of the brain should again become congested. To effect this, I gave him the five-grain doses of the sulphate of quina, and I gave it him every four hours, because, the fever being quotidian, I wished to get down a quantity sufficient to make such an impression on his system as to prevent, if possible, the recurrence of the paroxysm on the next day.

You saw that it succeeded, that he never had any recurrence of paroxysm after that which was on the day he came in. At the expiration of ten or eleven days the frequency of the dose of quina was diminished to six hours, and, three or four days afterwards, to every eight hours. I did not think it prudent to make an earlier reduction, on account of the habit of recurrence having been established during eleven months, and therefore considered it necessary that the impression of the quina should be maintained on the system sufficiently long to prevent the probability of return, a result I have not unfrequently witnessed where the remedies have been too early discontinued.

Well, then, my reason for giving him the blue pill was the vitiated state of the secretions, as shown by the dark colour of the motions, and also as an adjuvant to diminish any congestion or inflammation going on in the brain. These are the principles by which I was governed in the treatment of the case, and they are those which long experience has satisfied me will be most successful.

Now why did not this man get well during the three weeks that he was an out-patient at another hospital? From the description he gave of the taste of the medicine when first asked by me what he had been taking, there could be no doubt but he had taken quina, and, in addition to the quina, he said that he had also taken, every other night, two pills which purged him moderately. On the day that I discharged him, some of you will remember, that I expressed my curiosity again to know how much quina he had taken for a dose in conjunction with those pills, and the man overhearing me searched in his pocket and produced his out-patient's ticket with the prescription written on it. It appeared that he had been taking two grains of calomel with eight of compound extract of colocynth every other day, and *one grain* of sulphate of quina *three times a-day*. In one respect, gentlemen, you will observe that the principle of the prescription was similar to my own,—there was mercury and there was quina; he took them, then, and the disease continued. Why did it continue?—First, because the congestion in the head was disregarded, and, secondly, because the quina was given in an *inefficient* dose, a dose almost ridiculous, both as regards quantity and frequency, where ague has existed nearly twelve months. At the same time I ought to observe that I do not believe that even a much larger dose would have succeeded until the congestion had been relieved by local depletion.

Now, in drawing your attention to this fact, gentlemen, you must not imagine that I am endeavouring to take credit to myself for any novel practice. I wish merely to impress on your minds what observation and experience have taught me to be true, that, in the treatment of intermittent fever, whenever you find proof of local congestion or inflammation in any internal organ evinced by pain, and, perhaps, by increased heat, and, where the part admits, augmented by pressure, you ought never to hesitate to deplete locally, either by cupping-glasses or leeches, so long as there is proof of the existence of such congestion or inflammation: of course the quantity of blood abstracted must in each case be dependent on the power of the patient. Should there be active inflammation or very extensive congestion, local bleeding will not be sufficient, and you must resort to general. At the same time, you must bear in mind that such local congestion is the effect of the cold stage of the paroxysm, that every occurrence therefore of this stage must necessarily tend to augment or reproduce such congestion, and that therefore, though your first object may be to relieve such local congestion by depletion, your next is to prevent its reproduction, by preventing as quickly as possible the recurrence of the paroxysm; and, to attain this end, never hesitate to commence giving the quina or other antiperiodic remedies at the same time that you deplete, and give them in such doses and

at such frequent intervals as will be sufficient to produce the effect you desire.

The next case was that of James Douglas, a labourer, *æt.* 50, who had been working in a marshy district, I believe in Essex, and who was admitted into King's Ward on the 20th of November; he had suffered under quartan ague for the last six months. The case-book states "his countenance to be characteristic of the disease; the tunica conjunctiva of the eye to be tinged with bile; complains of pain, which is increased by pressure, in the epigastrium and right hypochondrium; there is also some tension and hardness there, though neither the liver nor spleen can be positively felt enlarged; there is slight effusion into the cavity of the abdomen, evidenced by fluctuation, and for the last three weeks both legs have become anasarcaous; tongue foul; bowels, he says, are open; pulse 90, full." This was the state in which I found him at my first visit the day after his admission.

I directed him to be cupped over the right hypochondrium and epigastrium to \bar{z} xij., to take a scruple of our compound rhubarb and calomel powder every other morning, and gr. v. of sulphate of quina *6tis horis*; to be put too on milk diet.

Now the report of the next day, the 22nd, states that he had a paroxysm at the usual time; that of the 25th states there has been no return of paroxysm; has very little tenderness in the epigastrium; bowels open; tongue white, moist, and only slightly coated; pulse 74, rather weak.

On the 28th, abdomen had diminished in size; scarcely any tenderness in the epigastrium; legs much less swollen; plentiful secretion of urine; bowels open, motions bilious; tongue moist, and less coated; pulse 84, fuller; no paroxysm.

Dec 2. No pain or tenderness in abdomen, nor can fluctuation there be now detected; legs very little swollen; appetite good, and feels much better; gums tender; no paroxysm. To omit the rhubarb and calomel powder.

5th. Continues improving in every respect. To take the quina *8tis* instead of *6tis horis*.

9th. Doing very well, feels hungry, and directed to be put on full diet. The bowels being rather confined, and the swelling of the legs not quite gone, let him take \bar{z} j. of the compound jalap powder (jalap and supertartrate of potass) *alternis auroris*.

22nd. Quite well; discharged on 24th.

Now, you will observe, that the treatment of this case was very similar to that of the preceding: in the first the congestion was in the head, and therefore he was cupped from behind the ears; in the present the congestion was in the liver, and consequently he was cupped from the neighbourhood of that organ; but you will remember that, in the first case, I directed the quinine to be given every four hours, while in the second it was given only every six. Now my reason for this was, that the first being quotidian, I was anxious to

get down a quantity sufficient to make a strong impression on the system, and thus prevent, if possible, the recurrence of the next day's paroxysm. The disease, too, had existed eleven months. A sufficient quantity was thus taken, and, as I before stated, no paroxysm recurred after that which was on at his admission. But in the present case the type was different; and I considered that a sufficient quantity might have been taken, before the expected recurrence of the paroxysm, to have prevented it. I confess that I miscalculated the period; for, had I recollected that it was expected on the following day, I should have given it every *four* instead of every six hours; as it was, however, he had only one paroxysm after his admission.

The third case is that of a female servant named Kesia Dyer, *æt.* 39, admitted with quotidian ague Jan. 1, 1835. She had suffered under the disease six months, and had been confined to her bed during the last two months. At the time of her admission, the case-book states, she complained of headach and feeling of great debility; tongue dry and coated with a brown fur; slight cough, with some pain of chest. There is some tenderness on pressure over the whole of the abdomen, but more especially in the left hypochondrium, where the spleen can be distinctly felt increased in size, though apparently not very much. Countenance anxious, and of the hue peculiar to ague; eyes sunken; pulse 72, weak; no appetite. When first attacked was resident in a marshy district; legs oedematous. She was ordered by the apothecary of the hospital, Mr. Whitfield, to be cupped over the left hypochondrium to \bar{z} xiv., and to take gr. v. of sulphate of quina *6tis horis*.—Milk diet.

The report of the next day states—A paroxysm came on this morning at five o'clock A.M.; less pain in the splenic region; pulse 100, weak; bowels confined. Ordered to take an aperient powder of rhubarb and calomel.—To continue the quina.

3rd. Bowels have been acted on by the powder; tongue moist, covered with a white fur; pulse 110, stronger. Paroxysm again to-day, but came on at eleven in the forenoon, and lasted till two P.M.

4th. Paroxysm returned to-day at eleven A.M., but only lasted twenty minutes. Tongue cleaner; less thirst; no tenderness in the abdomen on pressure. To repeat the aperient powder.

5th. No paroxysm to-day. Feels better, and is more cheerful; bowels rather too much relaxed by the powder.—Continue the quina, and take *infus. catechu comp.* \bar{z} j. after each loose stool.

6th. No paroxysms. No occasion for the astringent; appetite improving; asks for better diet.—Beef tea *Ojss.* daily.

9th. Still free from return of paroxysm; going on very well; pulse 100, weak. Omit the beef tea.—A slice of meat daily instead.

13th. No unfavourable symptom; able to

get up, and, after being up, legs and thighs much swollen; general strength increasing; urine scanty.—Pil. hydr. gr. v. omni nocte.

16th. General health greatly improved; pulse now 72, full. As she was purged by the blue pill it was directed to be omitted; and as the secretion of urine still continued rather scanty, she was ordered to take hydr. c. cretâ gr. iiss., pulv. scillæ gr. j., opii gr. $\frac{1}{4}$, ter die, and the quina to be diminished to three times a-day instead of four*.

Now, you will observe, gentlemen, that in this case the paroxysm returned three times after her admission, and I cannot help thinking that this might have been prevented had the quina been ordered every four instead of every six hours; but I shall have occasion to refer to this subject again in my next lecture, when I propose offering a few general remarks on the treatment of the different stages of intermittent fever, and have also a case of extensive disease of the uterus which I wish to draw your attention to. I shall beg, then, to occupy the remainder of our time to-day by saying a few words upon a subject, which, if not immediately connected with the treatment of intermittent fever, is still sufficiently allied to it to consider this a favourable opportunity for so doing.

As having the honour, gentlemen, of being a teacher in this school, I think it due to all of you, as well as to myself, to offer a few remarks on a critique which has appeared in one of the public Journals, in reference to the doses of certain remedies employed by me in the treatment of a case of periodical neuralgia. You are no doubt all of you aware that I have such a case in the female wards, and in which, in the hope of putting a stop to the returns of the paroxysms, I had employed both sulphate of quina and carbonate of iron, commencing with five grains of the former and two drachms of the latter, every six hours, and gradually increasing the dose of each until I arrived at the quantity of eighty grains of quina, and four ounces of the carbonate of iron, in each twenty-four hours; in addition to which, at a later period, a quarter of a grain of muriate of morphia was given in conjunction with each dose of the above named remedies, which was ultimately increased to a third of a grain. Still, however, the paroxysms, though mitigated, returned, and, abandoning the use of these remedies, I had recourse to the local application of aconitine in the form of ointment, with the most marked relief. The case was published, by my desire, in the *Medical and Surgical Journal*, simply in the hope of attracting public attention to a new and powerful preparation of aconite, which promised to be a highly useful addition to our *Materia Medica*.

* Jan 30th. She has continued this treatment, the kidneys have secreted abundantly, and there is now scarcely any anasarca of the legs remaining. She will be discharged next week.—REP.

The case was extracted from this Journal into the *Medico-Chirurgical Quarterly Review*; and I cannot do better than read to you the remarks of the Editor from his own book. Having detailed the case as published in the *Medical and Surgical Journal*, he says,

“In the foregoing practice there was exhibited *bold practice* in respect to doses. We know Dr. Roots well, and believe him to be a very judicious physician. We should have great confidence in his prescriptions, because we are satisfied that he acts under the guidance of observation and reflection. Eighty grains of sulphate of quina added to one quarter of a pound of carbonate of iron, with a strong dose of morphia, make altogether a ‘*quantum suff.*’ that would astonish a Bonhomme, a Quinn, a Hahnemann, or, indeed, any man who had not studied at St. Thomas’s Hospital. We remember full well the sensations which we ourselves experienced some years ago, when taking twenty grains daily of sulphate of quina for an intermittent. The tense feelings about the head, the “tightness” (as Dr. Philip would say) of the pulse, the constriction in the line of the intestinal canal, the *cordiness* (if we might use such an expression) of every nerve, and the painfully vivid operations of the mind, left an impression on the memory which can never be effaced. There can be no doubt but that difference of temperament in individuals makes immense difference in the effects of medicine; but we have so often remarked effects corresponding with those enumerated, in various individuals, that we confess some degree of timidity in the *heroic* exhibition of medicines. With respect to the carbonate of iron, we suspect that a drachm dose would be just as efficient as a quarter of a pound—perhaps more so. We acknowledge, however, that it is by experience and not by theoretical calculation that we are to be guided in these matters; and therefore we have put the foregoing case on record, from the practice of a talented physician, in order that it may excite the attention of our readers.”

Well, now, gentlemen, to some it might appear that in these observations there is something like a sneer intended—something like sarcasm—something ill-natured,—but I, who know Dr. Johnson well, who know his great candour, the singleness, nay, the extreme simplicity, of his mind, can assure you that such is not the case. With respect, then, to the boldness of practice with which I am charged, in respect to doses, I would observe to you, that our object in prescribing any remedy is for the purpose of producing a certain effect, and that, therefore, we ought always to adapt our means to the end we have in view. If a patient applied to you for your assistance suffering under simple constipation of the bowels, and for which you prescribed five grains daily of the compound extract of colocynth, and after the patient had taken it many days you found no action produced on

the bowels, would you feel that you were doing your duty to the patient—that you were acting in a way becoming men of science, if you continued to exhibit the same useless dose? If you prescribed fifteen or twenty drops of tincture of opium every night for the purpose of procuring rest, but without attaining your end, would you not consider that man little better than an idiot who still persevered in so ineffectual a dose? If it was your purpose to excite vomiting, and therefore prescribed fifteen or twenty grains of ipecacuanha without making any impression on the stomach, would you think yourselves justified in the repetition of a dose, to the influence of which the organ had already shown itself insensible? Would you not rather adapt your means to your end, and either increase the dose of either of the remedies I have alluded to, until you had produced the effect you desired, or seek for some more active substitute? This was the principle, gentlemen, that I acted upon in the treatment of the case which has elicited Dr. Johnson's remarks. I have found quina alone often the most efficient means of checking periodical neuralgia, and where that has failed, I have succeeded by giving it in combination with the carbonate of iron. As this was an obstinate case, I commenced the treatment with the union of both remedies, namely, five grains of quina and two drachms of the carbonate of iron every six hours. These doses, however, proving insufficient, I *boldly* (according to Dr. Johnson), but prudently (according to my own experience), increased *by degrees* the quantity of each until I arrived at that terrific dose of each, which has excited the worthy Dr.'s comments, and without any other distressing symptom in consequence of the dose of each, than that the stomach was occasionally oppressed, and for a day or so the medicine requiring to be omitted. Do not, however, mistake me, gentlemen, it is by no means my intention to recommend you to commence with scruple doses of quina, or ounce doses of carbonate of iron. But commencing with smaller doses, never hesitate to increase those doses to such an amount as your judgment and experience may have shown you that in other similar cases your success has been commensurate with the increase of the dose. With respect to the opinions of a Bonhomie, a Quinn, and a Hahnemann, value them as I do, not even at the twenty millionth part of the weight of a straw. Dr. Johnson says, gentlemen, that such doses are not only calculated to astonish the three above named gentlemen, but indeed any man who had not studied in St. Thomas's Hospital. Now this I consider as a high compliment to us all, for it shows that we have the reputation of being "*nullius in verba magistri*," that, despising this or that consecutus, or this or that dispensatory, as a guide for the doses or the remedies we employ, we alone own the dictates of judgment and experience as our guide in such matters.

In reference to the quantity of quina (eighty grains) ultimately exhibited in this case daily, Dr. Johnson has favoured us with an account of his own sensations, when taking only a fourth of the quantity in the twenty-four hours. He speaks of the tensive feelings about the head, the tightness of the pulse, the constriction in the line of the intestinal canal, the cordiness of every nerve, and the painfully *vivid operations of the mind*. I cannot say that it has occurred to me to witness such effects from quina; it is true I have met with some peculiar cases of idiosyncrasy, where even the smallest portion of quina could not be tolerated, but I have not observed generally more unpleasant consequences from forty, fifty, sixty, or eighty grains in the day than from twelve. The effect which I have most generally remarked from full doses of quina, has been that the patient has complained of a rushing sound, like that of water, in the head, and this has been produced to an equal extent by doses of three or four grains as by those of greater magnitude. But let me impress it on your minds, gentlemen, that if on the exhibition of this remedy you should meet with such effects as Dr. Johnson complains of in his own person, immediately omit it; you must be doing wrong, you are placing him in a condition unnatural to him, and it would be cruel to persevere. But do not let the necessity for the omission in such a case prevent your giving it in others, but ascribe it to its real cause, the peculiarity of that individual's temperament.

And now, gentlemen, with respect to the timidity to which Dr. Johnson confesses, in what he calls the *heroic* exhibition of remedies, I own to you that I did not consider myself as entitled to laurels because I dared to give as much as eighty grains of quina every twenty-four hours, after finding fifty, sixty, and seventy ineffectual. But it is only due to the worthy Dr. to call to your mind, that at a former period, when not oppressed by this timidity I presume, he gave eighty grains of calomel in twenty-four hours, and that therefore he had long since earned those laurels which he so kindly bestows on me. In that gentleman's excellent work "*On the Influence of Tropical Climates on Disease*," when speaking of dysentery, he commences with a most interesting account of his own case, written whilst surgeon of a man-of-war. He was bled, took castor-oil, six grains of calomel and one of opium, too, were given every five hours, which latter was subsequently given every four hours, and his medical attendant comforted him with the assurance that his malady would abate so soon as the mouth became affected by the mercury. In spite, however, of these six grain doses of calomel, the symptoms continued, nay, increased, the doses were inefficient, the means were not adapted to the end, and finding himself grow worse, and his gums still unaffected, he sent for his assistant, and desired him to bring him

twenty grains of calomel. He found no bad effect from this, but, on the contrary, he fancied that the tormina were rather lulled by it. Still, however, the desired effect was not produced, and again in two or three hours he sent for his assistant, ordered another scruple dose of calomel, and swallowed that, a few hours after which he fell asleep, and then relates, really in a most pathetic way, how he awoke free from pain, still fancying his state of comfort was only a dream. He then felt a call to use the night-stool; this made him fear that all his horrors were going to be renewed, but, on the contrary, he was delighted to find that he passed a copious bilious feculent stool with little or no pain. He then did that which every man possessed of such purely good principles would do, he uttered aloud the most sincere and heartfelt tribute of gratitude to heaven for his deliverance, and on getting into bed, he perceived that these two twenty grain doses of calomel had been sufficient to produce the effects which the smaller doses had been unequal to, that his gums were tender, and the saliva flowing freely from his mouth. He took no more medicine, and speedily was well. Was not this heroism, gentlemen? was there aught of timidity of large doses here? But let us see what was the result of this heroic practice on himself. When called upon subsequently to treat the same disease in others, he commenced with the ordinary doses which had been at first employed in his own case, but finding these small doses equally inefficient with others as they had been with him, he boldly resolved to adopt the same heroic treatment which he had found so successful in his own case. Accordingly, instead of six grains he gave twenty, once, twice, thrice, and occasionally even four times, in the twenty-four hours. So strenuously does the Dr. argue in favour of this *heroic* practice, that you will find it strongly urged through every portion of his valuable book. But, gentlemen, the greater part of you are no doubt already aware of this; most of you have read it, all of you I hope will read it, for it will well repay your time. It is true that, as the Dr. has observed with quina in large doses, he found these *heroic* doses of calomel sometimes productive of unpleasant effects, for he says, "in a few instances these doses produced great nausea and sickness at stomach, with *spasmodic* affections of different parts." Did the Dr., therefore, in consequence of these effects in a few, abjure its exhibition generally?—No; like a judicious practitioner he sought to combat these ill effects by the exhibition of opium and a diaphoretic, and he succeeded. So convinced was he of the efficacy of these *heroic* doses of calomel, that he has published a table in the work I am speaking of, to show the number of scruples that were in many instances taken before a cure was effected, and in one instance, as much as six drachms of calomel were taken in the space of seven

or eight days. It is only, too, of late years, I presume, that the Dr. has been less heroically disposed, for in the April number of the *Medico-Chirurgical Review* for 1826, page 328, when reviewing a work of Mr. Annesley's, entitled, "Practical Observations on the Effects of Calomel on the Mucous Surface of the Alimentary Canal," the Dr. commences his critique by saying, "Of late years certain *prejudices* and *erroneous opinions* respecting the *doses* of medicines have begun to give way. The Italian physicians have let in some light on this subject, and the medical men of the continent generally are taking advantage of it."

But, gentlemen, to return to the scruple doses of quina; understand that I did not reach that amount without having had previous experience of the safety, the advantage, and, indeed, the necessity for so doing, two examples of which I will relate to you, although they are mentioned in one of my clinical lectures which was published in the third volume of the *Medical and Surgical Journal*, 1833.

The first was a case of quartan ague, admitted some years ago into this hospital under Dr. Elliotson but treated by me, Dr. Elliotson being abroad; five grains of quina three times a day were first employed, but without effect; the dose was at last gradually increased to ℥j. still the paroxysms returned at the wonted hour. Arsenical solution was then given in conjunction with the quina, in ten minim doses; so that he took one drachm of quina and thirty minims of Fowler's solution daily. Dr. Elliotson returned just as the remedies had reached this amount, and finding that, spite of these doses, the ague continued, he ordered the patient to take the medicines *four* times a day, instead of three, and the ague directly ceased; remember, it refused to yield to a drachm of quina and half a fluid drachm of arsenical solution, but was instantly overcome when the former was increased to *four* scruples and the latter to two.

The second case occurred in my private practice about six years ago.

I was consulted by a lady in Wimpole-street, a West Indian, suffering under intermittent neuralgia of the supra-orbital branch of the fifth nerve, preceded by a slight rigor; the pain came on every morning at eight o'clock and lasted till two in the afternoon. She had suffered under the disease several weeks, and, under the idea that it was arising from hepatic derangement, had been at Cheltenham for a month, where she had undergone the discipline of calomel, blue pill, Cheltenham waters, and leeches to the temple. Still the neuralgia returned as severely as before, and at the same hour. Now three grains of quina given every four hours were sufficient to stop the return; and she remained free from it for more than two months, but having taken cold one evening in coming from a party, where the heat of the rooms had been great, the neuralgia returned the next day. I was

again desired to see her, prescribed again gr. iij. of quina every four hours; made no impression; increased the dose to five grains, and it speedily yielded. She now remained well for nearly three months, when she visited the Colosseum on a cold day, with an easterly wind, to which she was exposed on the top of that building for half an hour; the next morning the usual rigor and neuralgia returned. Now in this third attack I found five grain doses of quina every four hours perfectly useless. I increased it to seven, ten, fifteen, but still without the slightest effect in preventing the recurrence of the paroxysm. I then increased the dose to ℥j. and she immediately got well, and remained so up to the time of her return to Demerara, a period of twelve months after. So that in this case ʒij. of quina were taken in each 24 hours, forty grains more than the quantity which has excited Dr. Johnson's remarks. Did the result justify this increase of dose, or not, gentlemen?

It is well known, too, to most of our military and naval medical officers, that prior to the discovery of quina, the intermittents of the West Indies often required most enormous doses of bark to be given before they could be controlled, and I recollect the late Dr. Dunkin mentioning an example of the major of one of our regiments taking ultimately the monstrous quantity of a pound of powdered bark daily, a fact which the major himself corroborated upon my accidentally having been introduced to him.

I come now, gentlemen, to the last of Dr. Johnson's critical remarks; he says, with respect to the carbonate of iron, that a drachm would be just as efficient as a quarter of a pound, perhaps more so. If this was a practical truth, then have I been guilty of a double offence, I must have wasted the funds of the hospital, and loaded my patient's stomach unnecessarily, to say nothing of misleading those gentlemen who may have been following my practice for the purpose of guiding their own hereafter. Now I am quite ready to admit that if I prescribed carbonate of iron, merely for the purpose of increasing the colouring matter of the blood, that I should expect quite as much advantage from even half Dr. Johnson's quantity for that purpose, as from an ounce or a quarter of a pound; but this is a purpose for which I am rarely in the habit of using this preparation of iron; the diseases in which I am most commonly in the habit of using it are those belonging to the class neuroses, and I will take chorea as my chief example. I am quite satisfied that there has been no case of chorea admitted into this hospital under myself or under Dr. Elliotson, that has not been discharged from the hospital cured; if any of you know of such an instance, I will thank you to inform me (the reply was that no example was known). I know of but one instance of death in this hospital of a patient suffering under chorea, and that took place not from the chorea, but with the chorea,

for, upon a post-mortem examination, most extensive fungoid ulceration was found in the bladder, with abscesses in both kidneys, in addition to which extensive effusion had taken place in the brain. Now the remedy that I am principally in the habit of employing in the treatment of this disease is the carbonate of iron; and I have no hesitation in stating to you my conviction that the successful result of the cases has been the consequence of a necessary increase, from time to time, of the dose of the remedy.

I have taken a patient into the hospital suffering under this disease, I have prescribed a drachm, or perhaps two drachms (which I am most commonly in the habit of doing) every six hours. In a day or two my patient has been better, but if I have persevered in the same dose so long that amendment has become stationary, if I have persevered still longer in the same dose I have found my patient retrograde, but if I have increased the dose from two to three drachms, or have given the two drachms every four, instead of every six hours, I have invariably found improvement commensurate with the increase of the dose, as soon as the disease has become stationary. Most, if not all of you, can bear witness to the truth of my assertion, but as I always think one fact is worth a thousand assertions, I will just mention a case, which one or two of you perhaps may recollect:—A young girl, *æt.* 17, was admitted between two or three years ago, under my care, into this hospital, suffering under the severest form of this disease I remember ever to have witnessed. It had arisen from fright; she was out at a latish hour in the evening, and received a tap on the shoulder from some naughty old man, accompanied by an indecent proposal; from that moment she became the subject of St. Vitus' dance, and, after suffering under it some time, was taken, as I afterwards learned, to Guy's Hospital, where she remained several weeks; being no better she quitted it and came to St. Thomas's; the convulsive motions were so violent that it was necessary to strap her in her bed to prevent her falling out, and it was a work of extreme difficulty to the sister of the ward to watch her opportunity to put food into her mouth by means of a spoon, so little power had she over the muscles of her jaw. While I was in the act of prescribing for her for the first time, one of the pupils present hearing me direct the carbonate of iron to be given, said "Oh, sir, she has tried that without any advantage;" and it was then for the first time that I learned that she had been in Guy's Hospital. On enquiring the dose and frequency in which that remedy had been administered, I found that two drachms had been given twice a-day, ordered, as I understood, on the day of her admission there, and had never been increased until she quitted that hospital; I did not, therefore, hesitate to say to him, that the remedy had not been fairly tried, and that if he would take the trouble of

watching the case he should find that she should get well under that remedy, and that remedy alone, though differently employed. Two drachms were therefore directed to be taken every six hours, there was slight improvement, it was then ordered to be taken every four hours, there was greater improvement; she continued this plan for some days, and the disease appearing stationary it was increased to three drachms; it was thus, as circumstances appeared to demand, increased a drachm for each dose, whenever the disease appeared again to be stationary, and each increase of dose was attended by a correspondingly marked increase of improvement, until at length she took as much as one ounce every four hours while awake, and, at the expiration of between eight and nine weeks, quitted the hospital perfectly well. I could multiply these cases, gentlemen, if I chose, but it would be taking up your time unnecessarily. You have had, and will have, ample opportunities of verifying my statement.

Do not however imagine, from the illustration that I have brought forward, that carbonate of iron ought necessarily to be employed in every case of chorea, I am referring only to those cases, and certainly they form by far the greater majority, in which its exhibition may be proper. And I shall take an opportunity of occupying your attention upon this subject before the close of the present session.

I trust, gentlemen, that what I have said may have absolved your minds from any doubts as regards the propriety of the doses I have employed, which Dr. Johnson's remarks might by possibility have created; I think I have some right to claim to myself some small knowledge of both the doses, and the effects of all the remedies we employ. I have had 25 years of practical experience in my profession, during many of which I was attached as physician to three of the largest institutions in this metropolis, which furnished me with never less than eleven, and often with twelve, thousand patients annually, for whom it was my duty to prescribe.

ROYAL INSTITUTION.

THIS valuable Institution commenced its meetings on Friday, 23rd Jan., when Dr. Faraday delivered a lecture "On Radiant Heat," illustrative of the discoveries of Signor Melloni, a young Italian philosopher residing at Paris.

The learned Professor remarked, that as all his auditors must be well acquainted with the chemical phenomena of combustion, the source of light and heat, he should not occupy their time on that subject, but should rather direct his observations to the rays of heat, their nature, and the manner in which we became sensible to them.

We become aware of the presence of heat by its power of expanding objects; the usual way of proving this is by applying heat to a

glass bulb, full of atmospheric air, and continuous with a tube containing any liquid. The effect of heat is to expand the air in the bulb, which consequently enters the tube, and displaces the liquid. The experiments that have been made hitherto have all been performed with this instrument, but the Italian philosopher did not like to employ it, as he did not consider it sufficiently accurate to ascertain the presence of heat, and accordingly he made an instrument similar to this (*placing his hand on one on the table*), but on a smaller scale. It consists of two metals, in this instance antimony and silver, joined together by wires, with a magnetic needle attached. If one of these junctures were warmed, an electric current runs round the circle, and the needle is set in motion; previous to the application of heat it was stationary, and, as the metal cools, it reassumes its former situation. If the instrument be formed of successive portions of metals, as first antimony, then bismuth, then again antimony and bismuth, and so on, the effect will be very much increased, and the operator will be enabled to test a much smaller degree of warmth.

M. Melloni has been enabled, by means of this instrument, to settle a point which has long been considered doubtful by philosophers, that is the intensity with which the rays of heat pass through a body. If a plate of glass be held to the fire, the rays of light will be observed to pass through it as rapidly as through the air, but it is not equally the case with the rays of heat, and hence plates of glass are frequently used by noblemen and princes in their palaces to guard against the inconvenience of large fires, while the genial warmth may be diffused through the apartment. Let an experiment be made with a piece of rock-salt, and it will be found that the rays of heat will pass instantaneously through it, without warming the body they pass through.

Let any sort of light,—a lantern will do,—be employed, and different bodies placed within its rays, they will then be found to possess different properties, which are expressed by the terms transparency, translucency, and opacity. Glass will serve as an illustration of transparency, rock-salt and wax, of translucency, and the metals, of opacity.

By having recourse to similar experiments the rays of heat will be found to possess analogous properties, which have been termed by Signor Melloni *diathermal*, in contradistinction to *diaphanous*. To illustrate the meaning of what has been just advanced, take any source of heat, a naked lamp for instance, and place it at a certain distance from the pile, (the thermometer of Signor Melloni, which he has designated the *thermo-multiplier*, the *galvanometer* *), so as to bring it to 100 degrees,

* Described in the commencement of this abstract as composed of two metals, connected with wires, and having a magnet attached.

then place screens between it and the pile, and the action of the magnetic needle will indicate the quantity of the rays of heat transmitted by the medium employed. If a piece of glass be the screen it will not offer any interruption to the passage of the rays of light, but it will exert great influence on the transit of the rays of heat. Alum again will allow a different quantity of radiant heat to pass through it, and we shall find also a difference in the amount transmitted, if rock-salt be the body intervening between the rays of heat and the pile. Colour appears, perhaps, to exercise some influence on the quantity of heat thus passing, as will be proved by the following statement:

If the pile be brought to 100 degrees, by means of a lamp, and a piece of flint glass then intervene, 65° only will penetrate, if plate glass, 60°, crown glass, 50°, and green glass, 23°. But a very marked difference has been found to exist in different bodies, all of which are colourless, rock-salt will allow 92° to pass, Iceland spar, 62°, carbonate of lead, 52°, sulphate of baryta, 33°, borax, 28°, sulphate of lime, 20°, fluor spar, 15°, tartrate of soda and potash, 12°, alum, 10°, and, finally, although certainly not to be classed among the colourless bodies, sulphate of copper, 0°.

As an illustration of this, the following experiment was performed:—A piece of glass, which was very thin, while the rock-salt used was considerably thicker, the disadvantage therefore being on the side of the latter, were passed between the lamp and the pile, and it was ascertained that the glass transmitted more rays of light, and is consequently *diaphanous*, the rock salt allowing the rays of heat to pass more freely, and is therefore *diathermal*. Glass may be said to be transparent to light but opaque to heat, rock-salt opaque to light and transparent to heat.

The very dark-coloured quartz, called black quartz, will not permit the rays of light to penetrate it, but those of heat readily pass through, and the same may be said of black mica,—so that there are some bodies which are transparent to light, and not to heat, as glass; and some to heat and not to light, as black quartz, mica, &c.

Another point, which this Italian philosopher has endeavoured to prove, is, that light and heat are totally distinct; the theory of the present day is, that they are the same in principle, but Signor Melloni considers that they are essentially different, and he supports his opinion by the fact just mentioned, that some bodies are permeable by heat alone, others only by light. Dr. Faraday does not go with him throughout in his opinions.

Some illustration of his discoveries, relative to colours, were then offered, and, in doing so, Mr. Daniell's apparatus for burning lime was made use of.

[In prosecuting this experiment the theatre was darkened, and a solitary ray of light, that from the apparatus, was visible. With the aid of the prism, Dr. Faraday bent this ray,

at the same time separating it into the primitive colours, and he then showed the effect of passing different glasses between the apparatus and the wall, one kind leaving only the blue and some of the violet, another abstracting all but the green and a little of its yellow, and a third taking all but the red. In order to illustrate more forcibly the connexion of the ray proceeding from the apparatus with the spectrum on the wall, Dr. Faraday altered the position of the apparatus, and directed the ray to the ceiling, and it could then be clearly observed proceeding from the instrument to the spectrum. The experiment was very evident, and had a very beautiful effect. He also demonstrated that if two pieces of glass of different kinds, namely, one removing the red ray, and the other the green or blue, were placed before the spectrum, the effect would nullify the ray, and no light would be seen.]

He afterwards remarked, Signor Melloni has endeavoured to establish the same thing with regard to heat. He took two plates of alum, and found that the rays of heat passing through the first plate will also penetrate the second; but if the second plate, instead of being alum, should be of glass, the rays will be arrested in their progress, and not pass through. Supposing one hundred rays of heat were to pass through the first plate of borax, seventy would be transmitted by the second, were it also of borax, but if it were alum, only eleven would pass, and it is the same with all other bodies, so that if two plates are used, it is necessary that they are both of the same substance.

The refraction of light may be proved by a simple experiment. If a piece of silver, a capsule, be placed at the bottom of a basin it will be hid from sight; it is surrounded by the atmosphere, but when that is displaced by water, without in the least disturbing the position of the capsule itself, it will gradually become visible. This is owing to refraction of the ray of light; the ray passing from the air into the water is suddenly bent downwards, and thus renders the object visible.

It has always been a very difficult matter to refract heat, but Signor Melloni has been enabled to effect this object, by availing himself of the transparency of rock salt for heat. He found that glass was not sufficiently translucent, and he therefore employed a prism of rock salt, with which he was enabled to refract the rays of heat in the same way that refraction of light takes place, and he could do this not only with the rays from a lamp, but even with those from hot water.

In conclusion, the Professor made a remark relative to the polarisation of light, in allusion to the experiments of Mr. Forbes, of Edinburgh. A ray of light, he found, would pass readily through a plate of tomentine, and also through a second, if in precisely the same position, but if the situation of the second plate be changed even slightly, the passage of the rays will be arrested. Rays of heat will

pass readily, even under those circumstances where the rays of light are arrested.

In the preceding abstract of a highly interesting lecture, we have endeavoured to give the pith of the discourse, without attempting to follow the exact language employed.

When the lecturer had concluded his remarks, he directed the attention of the meeting to a fine bust, by Chantrey, of John Fuller, the munificent patron (for such he really was) of the institution. The inscription bore, "John Fuller, who gave ten thousand pounds for the promotion of science in the Royal Institution." In the library we saw a fine portrait, by Pickersgill, of the late Earl Spencer, many years President of the Institution. On the table, also, besides several mineralogical specimens, and two instruments for parallel motion, there were a cast of a fossil head of a bird preserved in the Ashmolean Museum, anatomical and scientific works and plates, and also specimens of spectacles for riding and for strabismus, made under Mr. Curtis's directions. The principle on which they are made consists in having the oval space for the eyes larger, and the substance filling it up convex, so as to resemble the anterior part of the natural eye.

Dr. Ritchie delivered a discourse on Friday, the 30th, giving a "Comparative View of the Newtonian and Undulatory Theories of Light."

Reports of Societies.

MEDICO-BOTANICAL SOCIETY.

January 27th, 1835.

THOMAS EVERITT, Esq., Professor of Chemistry, in the Chair.

THE announcement of presents this evening was rather lengthy; numerous additions have been made by members and others to the herbaria and cabinet of materia medica. A collection of indigenous plants was presented, put up in a very beautiful manner, each plant being named according to its scientific and its common nomenclature, the name of the month in which it was gathered, and the nature of the ground where it grew, being also mentioned. Had the donor added the class and order, according to Linnæus and Jussieu, and the medical virtues, where such are in existence, the present would have been invaluable; as it is, it forms a most important addition to the collection of dried specimens in the possession of the Society.

After some further business had been gone through, Dr. Ryan, the Professor of Materia Medica, proceeded to read what he called a "Comparative View of the Organic and Inorganic Systems, showing also the differences between plants and animals, and between *animals and man*." A more complete failure we have seldom been unfortunate enough to

witness; page after page of the manuscript was skipped "in order not to fatigue the Society," and what was read was certainly not worth listening to. One of the principal distinctions made between organic and inorganic bodies was that the latter increase by *chance* or *hazard*, while in the former the different sexes contribute to the perpetuation of the species. The Doctor must have been hard pushed when he gave such a definition. Again, he only produced one distinctive mark between the vegetable and the animal kingdoms, and that one was worthy the author of the "Lectures on Population," and of the forthcoming work "On the Perpetuation of the Species." He said that plants were distinguished from animals, inasmuch as to produce fecundation they do not have recourse to intromission, that is, a close union of the sexes does not take place! *Proh pudor!* Could no other example have been chosen? Considering that the majority of the audience at this Society are non-professional men, it was a bold flight, but somewhat of the Icarean character, and we may venture to predict that the attempt will not be repeated. The conclusion of the subject, the difference between *animals and man*, was postponed to a future evening, and dearly do we hope to be present, in order that we may be made aware of the difference; for, previous to the Doctor's promise to point it out, we did not believe in its existence. We are exceedingly anxious to know by what figure of speech, whether Hibernian or Gascon, or by what peculiar species of ratiocination this "cultivator of science," to use a favourite phrase of his, will prove that *man is not an animal!* As we have already remarked, hitherto he has been considered such, but it is possible that the Doctor has some new lights upon the subject, with which he will doubtless favour the scientific world. In the meanwhile we take our leave of him, and proceed to more useful matter, protesting, most energeically, we never yet heard such exquisite *nonsense* doled forth by any man, except when the same lecturer, some months since, delivered his opinions on the *effects of strychnine*. He will understand what we are alluding to.

The remainder of the evening was occupied with the consideration of the therapeutic properties of the *Ballota lanata*, a specimen of which had been recently received from Vienna. Dr. Negri observed that Professor Brera had published an account of this plant in an Italian periodical, from which it appeared to possess considerable influence in the treatment of chronic rheumatism. It was given in the form of decoctions, $\frac{3}{4}$ ss. of the plant (gradually raised to 3vj., and even to $\frac{3}{4}$ j.) being boiled in $\frac{3}{4}$ xij. of water down to half a pint. This being strained, half was administered night and morning with good effect. It appears to act on the urinary organs and on the skin, causing a burning heat of the integuments, then profuse diaphoresis, followed by

increased diuresis, the fluid passed being of a high colour, and depositing a red sediment on standing.

The account of the plant which was sent from Vienna with the specimen stated that it possessed analogous properties with colchicum, acting one while on the bowels, another on the skin, and sometimes on the urinary organs.

Dr. Johnson felt desirous that some of the plant should be procured, in order that its real properties might be essayed, as he considered it extraordinary that increased micturition should be produced, the urine being high-coloured and sedimentous. Where the secretion of the kidneys is scanty, it is high-coloured, and deposits a sediment; but when it is more abundant than usual, it becomes uniformly limpid; at least he had always found it so, and would be obliged to any medical man who had seen any case where the contrary was the fact.

It was soon after announced that Mr. Burnett, the Professor of Botany, would, if his health continued to improve, deliver a lecture at the next meeting, which would be held on Tuesday, February the 10th.

LONDON MEDICAL SOCIETY.

Monday, February 2nd, 1835.

EDWARD LEESE, Esq., V.P., in the Chair.

Hooping Cough.

The principal speakers were Dr. James Johnson, Dr. Burnes, Dr. Leonard Stewart, Dr. Whiting, Dr. Uwins, and Dr. Negri;—Messrs. Clifton, Dendy, Headland, Moore, Greville Jones, and Leese.

The subject of hooping-cough was resumed this evening, in consequence of a dearth of other matter, after having formed the subject of debate for several preceding evenings. Very little additional information was elicited, notwithstanding there was a greater number of speakers than is usually the case at this Society.

Mr. Clifton commenced the discussion by remarking that he always cured hooping-cough by restricting his little patients to an apartment of an equable temperature—from 54° to 60°. By a perseverance in this plan for about a month or six weeks a cure would generally be effected. He remarked that hooping-cough was never considered a serious complaint in summer, and this was making an artificial summer in winter; of course it was only applicable previous to any inflammation manifesting itself.

Several members spoke partially in favour of this plan, but some of them did not appear to place entire confidence in hygiene alone, but were inclined to have recourse to medication in conjunction with it. Mr. G. Jones alluded to the experience of Mr. Whitmore of

Cold-Bath-Fields, who, he said, was very much inclined to trust to a similar plan where it could be adopted, but employed a higher degree of temperature. Dr. Burne spoke of the necessity of guarding against injury to the brain from the shock produced by the violence of the cough: he had seen it cause insensibility, lasting some hours, in two cases. The preventive measures he would recommend were moderate depletion early in the disease, soothing medicines, a total proscription of animal food, and attention to the bowels.

Dr. Uwins ascribed the disease, in the first instance, to an affection of the nervous system, and more especially of the pneumo-gastric nerve. He recommended change of air as a valuable adjunct in the treatment of the complaint, and mentioned rather a curious fact in illustration. He stated that three of his children had had hooping cough, and he immediately sent them to Royston, the air of which, as every one knows, is *sharp and bracing*; here they soon lost their cough. Shortly after they paid a visit to an uncle in Suffolk, where the air is *mild*; while on this visit the complaint returned, but disappeared again when they went back to Royston.

Dr. Whiting had ascertained that the return of the cough was owing to an accumulation of phlegm. After a fit of coughing he had listened to the respiration, and there was no mucons râle, but in a few minutes it commenced, and kept gradually increasing. The little patient for a time would be quiet, and then would commence hacking, as if to relieve itself of the phlegm and to avoid the cough, which, however, at last supervened, and then the mucous râle would be absent for a time. In hooping-cough, when spontaneous vomiting took place, a favourable result was always expected. He would suggest small doses of the antimonium tartarizatum, therefore, in these cases, about one-twelfth to one-twentieth of a grain. He had given it in this manner some years ago to a child, and he found it improve the appetite and increase the strength of the patient, and he had since employed it as a tonic, and considered it one of the best we possess.

Dr. Negri confirmed the statements of Dr. Whiting as to the efficacy of antimonium tartarizatum in small doses in hooping-cough, but denied, most positively, its efficacy as a tonic; on the contrary, he believed it to be one of the most debilitating medicines we possess, and it could only be considered a tonic in the same way that bleeding, by lessening congestion, would relieve the circulation.

Dr. Whiting explained that he only considered it a tonic in the small doses he had mentioned, but Dr. Negri declared he believed it to act as a debilitating in all doses.

Reviews.

Records of General Science. By R. D. THOMPSON, M. D., with the assistance of THOMAS THOMPSON, M. D., F. R. S., &c. No. II. February, 1835. With Three Woodcuts. Taylor.

THE observations we made on the appearance of the first number of this Journal, showing its high importance and value to the medical practitioner, need not another repetition. The present number, it will be sufficient to state, is not inferior to its predecessor.

The first article is a "Biographical Account of Alexander Volta, by M. Arago." The biographer claims for Volta, and justly so, the merit of originating the Voltaic battery; though Lavoisier and Laplace succeeded in the first experiment, he shows that Volta "planned the means of discovery and the actual experiments, and is entitled to the credit of the success." After noticing the early periods of the life of Volta, describing the scene of his discovery, he is traced to Geneva, where "he founded a warm friendship with the historian of the Alps, who was well able to appreciate the value of his discoveries. That was a great age," marks the biographer, "when the traveller, without losing sight of Jura, could visit Saussure, Haller, Jean Jacques, and Voltaire. Volta, after an absence of a few weeks, returned into Italy by Aigue Belle, carrying with him, for the benefit of his country, that precious root, whose proper cultivation renders famine almost impossible." "The School of Pavia became the object of his attention, (Count Firmiali, the Administrator-General of Lombardy). He then established a chair of physics, and, in 1779, conferred it upon Volta. There Volta taught, for many years, numbers of young men, who congregated from all parts of the country, not indeed the mere details of science, which can be learned from books, but the philosophical discoveries, and those minute facts which escape vulgar intellects."

The whole essay is full of interest. To study the life of a great man is one of the most useful lessons that men can learn. He sees industry, perseverance, and talent surmounting all difficulties, and ultimately obtaining, if not riches, the respect and admiration, not only of his cotemporaries, but the renown of posterity.

After this we meet with a "Chemical Analysis of Shulite," an "Analysis of Arden Limestone," and the first of a series of papers entitled, "Notice of some Improvements in Science," by the Editor. One of these notices we shall extract; it is on a subject of which the world knows little, if anything.

"Acoustics.

"It has been recently observed by M. Breschet, that, in many of the chondropterygious fishes, as the skate, torpedo, &c., there are open

ducts, leading out externally, by which a communication is established between the centre and the membranous cavities of the labyrinth, while in many of the osseous fishes, especially the *cyprini*, or minnow tribe, and the *clupea*, or herring tribe, &c., an opening exists between the swimming bladder and the labyrinth. He has likewise detected in the sacs of the labyrinth in man and vertebrated animals concretions which he terms *otolites* and *atocopies*.—(*Ann. de Chim.* 56). M. Cagniard Latour has obtained some curious results from his experiments on the sonorous vibration of liquids, and has attempted to explain the use of the concretions observed by Breschet. In employing a glass tube one metre in length, closed at the bottom and filled with water, he found that, when rubbed with a moist cloth, a sound was produced, resulting principally from the longitudinal vibration from the column of water, yielding 790 vibrations in a second. A syphon, open at both ends and filled with water, under the same circumstances, afforded an acute sound. Hence we can account for fishes hearing in cases where their auditory organs contained no gaseous matter. He tried the effect of vibrations upon other liquids. Several substances more dense than water afforded more acute, others more grave, sounds than that liquid. Among the first are carbonate of potash at 71°, and muriate of lime at 87°; among the second, sulphuric acid at 150°, sulphuret of carbon, and mercury. The same observation holds with liquids possessing an inferior density to water. He concludes,—1. That the liquids in human ears are contained partly in species of tubes. 2. That these tubes or canals are osseous. 3. That the semicircular canals have a curvature answering to that of the syphon. The sound appears to be increased by introducing a solid in contact with the water; for, with a water-hammer containing several small rounded stones, the globular vibration of the liquid took place without requiring to have any impulse communicated to it, as with the common hydraulic hammer. Hence, he conceives, that the concretions in the labyrinth may facilitate the globular vibrations of the liquid in which these bodies are suspended. Latour and Breschet are both engaged in the further prosecution of this interesting subject. The latter is investigating the functions of the semicircular canals in the slug."

Then follow some interesting notices in the same essay, viz.—on Electricity; Magnetism; Pneumatics; Chemistry, in which is a table of the specific heat of bodies; Atmospheric Air; Compounds of some of the Gases; the method of procuring *selenium*, the nature of some of the acids, and of some of their combinations with metals, &c. After the "Improvements in Science," follow a number of treatises on curious topics to the geologist, mineralogist, and chemist.

A Treatise on Rickets; with a New Theory of Ossification, and a Plate and Description of an Improved Reclining Couch for the Distorted. By G. HUME WEATHERHEAD, M. D., Lecturer on Materia Medica and Therapeutics at the Westminster School of Medicine. Pp. 128. Second Edition. Reunshaw. 1835.

IN the preface Dr. Weatherhead commences by stating, that "In none of the systems of physiology, which I have seen, is there any theory of ossification; the progress of the process is minutely described, but the manner in which it is accomplished has never yet been attempted to be explained. The main component of bone is the phosphate of lime, this matter is continually being deposited by the secreting arterial capillaries, and again taken up by the absorbents, and yet the wonderful thing is, that the phosphate of lime is not soluble in the fluid from which it is abstracted, phosphate of lime is not soluble in blood."

Our author has endeavoured to explain the paradox, and with what success our readers shall judge. After discussing the chemical composition of bone at the different epochs of life, the mode of development and the priority and succession of perfect formation in the different bones, we are brought to the subject of rickets, divided into infantile and adult. From the following observations we should suspect the Doctor to be averse to civilised life. "But where is it to be found? Are we not all children of nature? Is there a wide difference between the black, now but just emerging from slavery,—that people, which formerly shed the light of literature and science in Asia, whence it was reflected into Europe,—and is now receding, we hope, to its original abode. We are all savages, we tear, lacerate, and feed upon each other like the inhabitants of the deep! We differ in mental proclivity and bodily vigour, but we are all subject to the same "ills that flesh is heir to."

"Rickets is distinctly a disease in the train of civilised refinement, for nature, when acting unshackled by the trammels of art, and uncorrupted by the devices of luxury, rarely denies to man the regular proportion of his limbs. The savage, who, wild and uncontrolled, freely ranges the forest, is noted by all for the regularity of his form, the activity of his body, and the health and vigour of his constitution. It is the pampered progeny of excess, indolence, and debauchery, that are the martyrs of diseased indulgence."

The different changes in the configurations of the skeleton in rickets are enumerated, and the author's views on the most advantageous treatment to be adopted, in the infantile as well as in the adult affected with this disease.

On the theory of rickets, Dr. W. states, after making some general observations on the agents of secretion and absorption, and on the composition of bone and the elements of blood,

that "the phosphate of lime is the earthy matter giving solidity to the bones; but the phosphate of lime is nearly, or entirely, insoluble both in water and in blood, nevertheless, all must grant that it is deposited from this latter fluid, and yet blood is not a solvent, as we have said of this earthy salt, then this earth cannot exist in the blood simply in the state of a phosphate. The super-phosphate of lime is perfectly soluble both in water and in blood, therefore our purpose is to show that it does exist in the blood in a state of a super-salt." The idea is exceedingly ingenious, we do not remember to have seen it before. The facts adduced we have not room to transcribe. On the treatment of rickets many useful suggestions are offered.

We notice a "reclining couch for the distorted," the plan of it seems good, it deserves putting into operation.

There are some curious points in the work, we would recommend the Doctor to further investigate them, and men, who read for knowledge, to peruse what is written.

An Address delivered at the Birmingham School of Medicine and Surgery, on the occasion of the passing of the appended Laws and Regulations. By JOHN JOHNSTONE, M. D., F. R. S.

It is gratifying to the lovers of science, to our profession especially, to see medical science emerging, as it were, from the trammels of trade, and endeavouring to erect, by the united exertions of its members, a noble superstructure for itself, but it is, moreover, interesting to see that in Birmingham the noble and the wealthy join hand in hand with the profession. It appears like another dawn of the sun of science, stretching out her rays from caverns that the vulgar would pronounce dark and dismal.

We have been so much interested with the perusal of the present address, that we cannot forego the pleasure of making the following extracts.

"I might here enter on a detail of the instruction imparted by this School, and the means of affording it; but you yourselves will estimate it from one fact. Since the anatomical bill came into operation, forty-three bodies have been permitted to be anatomically inspected, by the wisdom and just feelings of the overseers; and thus the most minute instruction has been imparted to the students. Judge of your own security, and of the security of the public, from such opportunities; and I am sure it must be a high gratification to those noble and honourable members of the legislature here present, to know that their views in enacting that bill have entirely answered, so far as our own experience goes, and that the prejudices against dissection have been mainly extinguished. It was for this purpose that we threw open our museum to the public gaze, and let me add the public admiration, during

the past month; and I am delighted to affirm, that not one instance of disregard to property, or of disrespect to persons, was manifested; and that of the thousands and tens of thousands that flocked through the museum, every one expressed his gratification, and his conviction that the museum has been furnished for the good of the community.

"I have thus brought the history of our School to the period of its having a fixed abode; though with many and great conveniences, yet far from complete. But even then, the chief subject of admiration to all was the springing up of the museum, as it were by magic. This, too, was chiefly the work of the mind and the hands of Mr. Sands Cox; and you who viewed it in its primitive state, what must be your opinion of his merits and exploits, now that you view it in its present advancement? The store of the most curious anatomical preparations, and those most useful for the instruction of the pupils—the wax models so unrivalled in beauty and exactness—the replenished state of the museum of natural history—the library—and, above all, the fitness as a whole, for its great purpose, the instruction of our pupils in the auxiliary sciences which administer to medical education.

"The house which you are called upon this day to consolidate and render permanent as a School by the laws you shall ordain, has been put into your hands by the public spirit of the two proprietors, the lecturers in anatomy and *matéria medica*; and rears its front no less a monument of their generosity than of their ardour in the promotion of science. To them though thus mainly indebted as proprietors, yet on the whole body of the lecturers the Institution must always chiefly depend, on their exertions, on their ability."

"Of the former lecturers who have resigned their offices, it cannot be deemed invidious for me to select the name of Dr. Pearson for particular mention; his age, his classical erudition, his research into medical lore, especially his diligence in exploring the properties and virtues of medicaments, his sagacity in discerning diseases, and that ardent thirst for knowledge which is the surest test of success in imparting it, need not the humble meed of my testimony—yet these were the qualities and accomplishments which made him so useful a lecturer in this School, and which so materially helped it on in its progress. To Dr. Booth like thanks are due; his large stock of medical acquirements, and his rare acquaintance with foreign medical learning, combined with his early patronage of the Institution, were precious advantages, which were afterwards continued by his clinical lectures. It was said by an illustrious man, on an occasion which must have stirred up the whole soul of his compatriot auditors to sympathy and tenderness,

Ἀνδρῶν γὰρ ἐπιφανῶν πᾶσα γῆ τάφος,

and so to elevated minds their own munificent and generous actions are a sufficient memorial.

But it is the duty of those who receive benefits not to forget them; it is even their business to record them, when they are of a public nature, and for the sake of posterity not to bury them in oblivion."

A MEDICAL ASSISTANT'S LETTER TO
THE LONDON MEDICAL AND SUR-
GICAL JOURNAL.

*To the Editors of the London Medical and
Surgical Journal.*

GENTLEMEN,—I am one of those almost helpless and degraded beings called "Medical Assistants." Long, in silence, and in common with hundreds of others as unlucky as myself, have I brooded on the hopelessness of my case, and hoped (how vainly!) that time would bring a remedy for our evil; but, alas! years after years have rolled away and left no trace of improvement in our condition. Can you wonder, then, if goaded by feelings nearly akin to despair, my solitary voice should be raised in the tone of complaint? No; I judge from the liberal sentiments uniformly expressed in your excellent Journal, that, so far from considering what I am about to say uncalled for, or condemning my motives, you will acknowledge their justness and sympathise in my suffering. The hand of oppression is strong upon us, and unless the medical press afford succour, where shall be our place of refuge?

Would you, gentlemen, believe, that after having served an apprenticeship of five or seven long years, in the dispensary or shop (as it may be) of a general practitioner, upon our emancipation from this state of vassalage, our services are worth no more than 20*l.* or 25*l.* per annum to any professional gentleman who may have occasion to employ us! and that, during our employment, no starling in a cage enjoys less liberty than we do! Very few among us can obtain a salary of 30*l.* or 35*l.*, and but a choice number, indeed, the (among us) almost unheard of sum of 50*l.* per annum! No matter what degree of ability we may possess, the helpless state into which the want of foresight in our parents or guardians has plunged us, admits of no alternative save accepting the miserable pittance offered in the shape of salary, or starving! If, perchance, a discontented victim venture to remonstrate with his principal on this inadequate pay, his soul is frozen within his body by the following reply: "Oh, young men like you should not enter the profession. I give as much as my neighbours, and, besides, are you not acquiring experience?" To the first part of this speech we can give no other answer than a shrug, but to the latter portion of it, about experience, the majority of us can conscientiously rejoin "we get little or none;" and if we did, and rendered ourselves more efficient, would our stipend be increased? No; what then is the value of the experience

our employers talk of, and for which, though a non-entity, they make us indirectly pay, by giving us such scandalously trifling remuneration? Alas, gentlemen, we are an ill-treated race, and, unless the legislature or public press take our part, a hopeless one. Should you do me the favour to insert this in your widely spread journal, you would confer an obligation on

A MEDICAL ASSISTANT.

REMARKS ON THE PAPER READ BY
SIR HENRY HALFORD AT THE
COLLEGE OF PHYSICIANS.

"ECCE ITERUM CRISPINUS."

"Gravedigger. Have you sold those ancient bones you wot of?"

"Old Bones. Aye, marry have I! and now come for a fresh stock."

Old Play.

IN our last number we intimated that we should make a few remarks on the paper delivered by the learned President of the College of Physicians, we now proceed to redeem our promise.

This was the first meeting for the season, and took place on the 26th ultimo. Every admirer of the science of medicine present could not but feel proud of the brilliant array of talent and consequence which graced this gathering of our *soi-disant* profoundest members, marking the increased estimation in which our profession is held. Two of the highest functionaries of this realm, the Archbishop of Canterbury and the Lord Chancellor, supported the learned President on the right and left. Nearly seven hundred persons, among whom were Sir Robert Peel, most of the Ministers, Judges, Bishops, and a host of smaller note filled up the imposing picture, all of whom *erectis auribus* awaited with intense interest the opening of the learned President's classical and ornate paper,—a paper, perhaps, suited to the mixed

auditory present, but we feel justified in saying exhibiting little research and less science. A rapid glance at the heads of the paper, which for its length was worthy of a better subject, will demonstrate the truth of what we have advanced.

The subject chosen was details connected with the decease of a few distinguished individuals of more modern times, the President having despatched the more ancient in a former lecture. The sketch began with Henry the Eighth, who, after having dragged himself into disease, finished his blustering career, the beautiful of "hydropsie" at the age of 56. Wolsey, to whom "Bluff Hal" gave (in his capacity of physician we suppose) some notable instructions how to evade the sweating sickness, died of a complication of dysentery and broken-heart, having first predicted the hour of his death. Edward the Sixth died of what very few could have survived, the sequelæ of measles and small-pox, which, in the succeeding year, after undergoing these diseases, aided by the efforts of an old woman, recommended to attend the King by the Duke of Northumberland, carried him off. Queen Mary, of persecuting memory, died of a sort of *double entendre*, her dropsy having been mistaken for pregnancy. The wily and puritanic Oliver Cromwell left this world quarrelling with his physicians, in consequence of a diseased spleen. Charles the Second died of apoplexy, after having been bled to sixteen ounces, cupped, purged up and down, swallowing twenty-five drops of spiritus humani cranii, and having the names of fourteen physicians appended to a prescription! King William, Prince of Orange, died of the consequences of pneumonic inflammation, brought on by a fall from his horse, which, breaking at once his collar bone and an old pleuritic ad-

hesion, accelerated the catastrophe. Mary, his consort, died of small-pox. Poor Dryden's dissolution was caused by ossification of the arteries of the extremities, which produces mortification. Demented Dean Swift, of unluckily facetious memory, left this world from a paralytic affection, the germs of which pre-existing in his frame in the shape of irritability, the learned Præses opines warred against his mental sovereignty and subdued it. An apoplexy carried off George the First, and George the Second died of a rupture of the right ventricle of the heart. On the mental, which preceded the corporeal death of George the Third, Sir Henry did not enlarge, so we at last come to the late Duke of Gloucester, the cause of whose death was seated in the liver, involving the stomach in so great a degree of irritability as to render it incapable of retaining the smallest quantity of food; of course nature unsupported closed his earthly career, and we could wish that the learned President also had in this point concluded *his* lengthy paper, instead of prolonging it into a funeral oration. His post-obit praises of the late Duke sounded like flattery, were in bad taste, and should, at all events, have been confined to that portion of his character, of which Sir Henry had had doubtless better opportunity of judging than many of his hearers. The public character of the Duke the public knows without any flourish of trumpets from the College of Physicians.

Of such materials, then, was the learned President's paper composed, and were Sir Henry a man of mediocre attainments, and driven for lack of genius to make his bill of fare a bill of mortality we should not quarrel with his taste, or condemn his spectral cavalcades of post-mortems, however we might deem their exhibition

fitter for the bone-house than for the arena on which they figured. We should have regarded this propensity for parading before our eyes the phantoms of the dead, each with his scroll of evil under his arm, as a matter not amenable to our criticism, had such propensity been fraught with no evil, nor lessened the utility of the man. But knowing as we do that Sir Henry possesses a highly cultivated mind, and talent of no ordinary stamp, we feel called upon to say, that his late lecture was not the homage science expected from him, more especially as she had lifted him to proud pre-eminence, and fixed him on a pedestal, whence he looks down on his humbler brethren. Such a lecture, we repeat, was not the offering she expected, and Sir Henry would do well to reflect, ere he delivers another, on the claim which the public has on those blessed with the power and opportunity to benefit it. Sir Henry well knows that the business of science, as well as of life, is to move forward, and must be aware that it would be more in keeping with the scientific dignity belonging to his order, to dilate upon some topic of more general interest and advantage than the one chosen. Were our humble advice to be received, we would counsel the learned President to abandon to the gravedigger the musty carcasses of olden time, which he has now, for the second time, raised from their rest, and ponder, as Sir H. Davy and a host of other illustrious benefactors to science have pondered, on what is truly great and useful.

If, as we have heard reported, Sir Henry, some time ago, proposed some scheme of Medical Reform to his brethren of the College, which they scouted, might not such a theme be advantageously considered on the next occasion? It would be, if not quite so grateful to the ears of

his auditory, as the history of men "whose brains are out," more instructive, and the moment chosen for its exposition would give it additional effect.

We conclude by assuring the learned President, that the silky tissue of his eloquence, more particularly when applied to the superfluous elucidation of what is already sufficiently clear, is not, in these times, the peg on which to hang either popular applause or the respect of the profession. Something more solid, more beneficial to the age in which he lives, is expected from his acknowledged talent; and if such good be incompatible with the empty tinkling of sounding sentences and nicely balanced periods, it should supersede them.

MEDICAL ASSISTANTS.

A LETTER which appears in the columns of our present number, subscribed "*A Medical Assistant*," seems to claim some attention, on account of the melancholy truths which the writer therein enarrates.

We have been long aware of the difficulties and mortifications under which this silently enduring class have pursued their weary and monotonous task, ill paid and ill treated in nine cases out of ten; no master-spirit has arisen among them to state their grievances or make their feeble voice heard beyond the humble precincts of their laborious occupation, and being, generally speaking (for there are a few of superior education), unblest with that share of information which make men restive under the lash of injustice and oppression, they have hitherto endured their heavy lot with a degree of patience and unostentatious fortitude deserving of a better fate. In no other pursuit to obtain a living is the re-

muneration so inadequate to the services performed as in the medical profession, in so far as regards assistants. In no other rank of life is the difference between the employer and employed so strikingly conspicuous; the former, perhaps, rattling in his carriage, with his annual return of from 500*l.* to 1500*l.* or more, contents himself with doling to the latter, who is perhaps as well qualified as himself, the wretched stipend of 20*l.* or 30*l.* per year, forgetful of his eternal captivity and noisome drudgery; forgetful, too, that from early dawn to latest night his assistant is engaged in that petty detail of pills and nauseous potions which fills his principal's pockets, but leaves his own as empty of coin as his frame is of spirit. No day of rest is known to this step-son of *Æsculapius*; not even the sacred seventh brings him the holiday that enlivens all beside, nor cheers him with a cessation of his toil. And for all this close application and ceaseless subservience, what is his reward?—A little food for which he can have little appetite, and from twenty to thirty yearly pounds!

Now let us see, by the test of comparison, whether there be any justice in this. A lackey or a valet, who needs no preliminary expenditure of either time, money, or scientific study, to qualify himself for the discharge of his duties, receives at least as much, and often far more, pay for less irksome services than the medical assistant can obtain, although he must undergo, before he can qualify himself for his bitter task, a considerable outlay of money, time, and study! Commercial clerks and linen-draper's fags put into their pockets salaries which would put to the blush our medical assistants' modicum, and have this farther advantage, that, according to their abilities, so

are they paid; while our medical assistant, be his capability what it may, can get, unless by some peculiar accident or good luck, no more than the niggard sum alluded to! It will be observed, doubtless, that for this strangely low rate of remuneration some cause must exist which ought to be no longer tolerated. Let us explore this cause.

Medical assistants may be divided into three classes: the first and most respectable consisting of young men having good friends or some property, able to pay Professors' fees, &c., but wanting experience, and unable to bear the expense of living independently while attending hospital practice; the second, of such as, after their apprenticeship, possessing no funds to pay for attendance on lectures, &c., seek, by becoming assistants, to scrape together so much of the indispensable as may carry them on in their studies; the third and by far the most numerous caste are such as have no chance of establishing themselves as principals, but whose ill-judging and ambitious parents have thrust without preparative education, by means of some needy practitioner to whom a 50*l.* premium was too great a temptation to be withstood, into the profession, the interested master, although conscious that future degradation and misery would be the lot of his ill-starred apprentice, withholding that information which might have arrested his fate, viz.—that when his term of *servitude* was accomplished, a term of *study* far more expensive was to be commenced and achieved, ere he could become a member of his profession.

It is these last that press like an incubus upon the interests of the worthy and well educated assistant. It is these who, crowding to the metropolis from every corner of the empire, resort either to Apothecaries' Hall or other medical agency offices to seek,

or rather beseech, for employment; and a mortifying and degrading sight it is for a lover of his profession to behold this *once* misguided, *now* desponding and hopeless portion of it, obsequiously attending, at nine o'clock every morning, the levee of the hall beadle, each willing, for a bare subsistence, to cut under his fellow-sufferer's demand, and sell himself, respectability and all, for whatever trifle may be tendered. The article, such as it is, becomes cheap because too plentiful for the demand, and the cause of this over plenitude is to be found in the laws relating to our profession.

These, thank heaven, must soon undergo the pruning hook of a more intelligent legislature than that which enacted them. The gap through which *all*, without reference to prior education, entered into and trampled on our honourable profession is about to be closed, and the soil, on which the legitimate plant now withers, weeded and cultivated.

To our correspondent we say, we commiserate his condition, and will, when the proper opportunity offers, endeavour to ameliorate it by advocating a better system. In the meantime, we cannot forbear making that appeal to which even-handed justice prompts us. Surely the more respectable portion of our brethren will take into consideration the efficient and indispensable services afforded them by their assistants, and, disdaining to tax them to the utmost for a niggardly recompence, anticipate by present liberality that scale of remuneration which most assuredly a salutary revision of medical law will not long hence bring about.

ACADEMIE ROYALE DE MEDECINE.

Sitting, November 18th, 1834.

Irritability of the Heart.

An account was given by M. Castel, of some experiments made by himself and M. Amussat. They tend to confirm the observations already made by physiologists, that pulsation is perceptible in the right cavities of the heart after the other parts have become completely motionless, whence it follows that in them life is the last extinct. Two theories have been advanced as explanatory of this phenomenon. According to the one, the greater irritability of the right side of the heart is considered as offering an explanation of, while by the second it is attributed to, the stimulating influence of the venous blood, which exists in abundance in the right auricle, while the pulmonary blood is no longer sent to the left side of the heart. The latter one was adopted by Haller, and has since been generally received. The result of the experiments of M. Castel induces him to support the first opinion. Considering the presence of the blood in no way concerned in the production of the phenomenon in question, and regarding irritability as influenced by nervous agency, he imagines the right side of the heart to be more abundantly supplied with nerves than the left. Though he has hitherto been unable to demonstrate this point by dissection, he intends continuing his researches, and laying the result before the Academy. M. H. Cloquet feels assured that the right cavities receive nervous filaments in greater number, though not of greater size, than the left cavities; the proportion may be considered eight or ten to five or six. We have the evidence of Scarpa and Walter of Berlin, in confirmation of this anatomical fact.

ACADEMIE DE MEDECINE.

Sitting, January 13th, 1835.

President, M. LISFRANC.

Observations on the Diagnosis of the different Scapulo-Humeral Dislocations.

BY M. MALGAIQUE.

The most modern surgeons who have written on the subject of dislocations, Boyer in France, Astley Cooper in England, Monteggia in Italy, and Chelius in Germany, agree in recognising three dislocations of the humerus, viz. the dislocations said to be below or into the axilla, where the head rests upon the margin of the scapula beneath the glenoid cavity, the dislocation inwards or forwards, in which the head of the humerus is lodged beneath the pectoralis major, and the

dislocation backwards, when the head is thrown into the infra-spinous fossa. A partial dislocation has also been described by Sir A. Cooper, in which the head is placed in contact with, and to the outer side of, the coracoid process. Consecutive dislocations from muscular action are recognised by most surgeons.

M. Malgaique discusses these various opinions; availing himself of the assistance of surgical and pathological anatomy, and of careful observations on both the dead and living subject. His principal deductions from the above sources may be brought under the following heads:—

1st. We have five principal dislocations of the humerus, and also numerous varieties of minor importance.

2nd. The most common is that in which the head of the humerus is placed beneath the coracoid process, the neck being in contact with the anterior margin of the glenoid cavity; to this belong all the signs imputed to dislocation into the axilla, or that which is considered to take place inferiorly. M. Malgaique names it the infra-coracoid dislocation, and has pointed out two new and important signs, viz. the protrusion of the head of the humerus beneath the great pectoral muscle, and the increased extent of the anterior wall of the axilla in its measurement from its free margin to the inferior border of the clavicle. Another new sign, though not invariably present, is the rotation of the arm outwards.

3rd. The true nature of the dislocation inwards does not appear to have been hitherto described. M. Malgaique, in accordance with two observations of his own, and another borrowed from White, considers it as characterised by the elongation of the arm, a sign also common, in his opinion, to all the dislocations of the humerus; a corresponding elongation of the anterior wall of the axilla, the closer approximation of the humerus to the trunk, the impossibility of discovering the head of the bone in the axilla, the protrusion of this head beneath the great pectoral muscle internally, however, to the coracoid process. The head is placed immediately in the subscapular fossa, the greater tuberosity is situated anteriorly, the capsule is lacerated to a greater or less extent. M. Malgaique applies the term subscapular to this dislocation.

4th. M. Malgaique has been able to discover but three cases of true dislocation downwards in the various authors, the chief symptoms being the elongation of the arm to the extent of nearly an inch and a half, and the evident situation of the head of the humerus beneath the glenoid cavity.

5th. M. Malgaique regards the partial dislocation of Sir A. Cooper as impossible, substituting one in which the articular surface of the head of the humerus partly rests upon the anterior margin of the glenoid cavity beneath the coracoid process; in this dislocation alone the capsular ligament may remain uninjured, though it is commonly ruptured; he names it

the imperfect infra-coracoid dislocation. He gives the exact symptoms, concluding, in opposition to the opinions of Cooper and Dupuytren, that it is not more subject to spontaneous relapse than any other.

6th. There is the posterior dislocation by which the head of the humerus is placed in the infra-spinous fossa, and beneath the acromion process, whence M. Malgaigne names it the subacromial.

7th. The idea of consecutive dislocations from muscular action is absolutely rejected by the author.

SOCIÉTÉ DE MÉDECINE PRATIQUE.

Sitting, December 4th, 1834.

Osteo-Sarcoma arising from a Blow.

BY M. ROSSEAU.

M. Rosseau presented the left half of the lower jaw of a cow, which was killed at the Jardin des Plantes for the nourishment of the inmates of the menagerie. The disease, which existed to a great extent, had been caused by a blow from the handle of a whip. Similar diseases have arisen in individuals who have received very violent blows, as in a child, who having been struck severely on the shoulder, an osseous tumour was there developed, which caused his death.

SOCIÉTÉ DE MÉDECINE DE PARIS.

November 7th.

President, M. ROCHE.

Encysted Abscess of the Pleura.

M. Pruz read the case of an old man in whom were found obliterated tuberculous caverns, an encysted abscess of the pleura containing osseous particles floating loosely in the purulent secretion, also many fistulous communications between the cyst and the bronchii. He concluded by expressing a wish that the Society would confide to some member the analysis of the various morbid products he laid before them, especially with a view to ascertain whether the concrete osseous substance be identical in its nature with true bone.

M. Guibourt was then entrusted with the chemical examination of the smallest of these unique productions, and the case was ordered to be printed in the records of the society.

The plague has broken out in Alexandria, quickly spreading into every quarter of the town. It first appeared on board the vessels of the line Nos. 1, 4, 6, and the frigate Behera. Great anxiety exists with respect to the arsenal where more than 8000 labourers are employed; consternation reigns throughout the city, and all the richer Mussulmen have adopted the most minute sanitary precautions. Twelve years having elapsed since its last appearance, it is feared terrible ravages will ensue; the misery of the lower orders is excessive.

One of the most remarkable Cæsarean operations was performed by M. Stoltz, of Strasbourg, on the 20th of last December. The age of the patient was 26 years, her stature was 44 inches, and the antero-posterior diameter of the pelvis was estimated at two inches and a half. A healthy infant was extracted, and the state of the mother gives every hope of a favourable result.

A Bavarian physician had departed this life, as was supposed by his professional brethren, in consequence of a vomiting of blood, and he was laid out in the customary manner. According to the laws of the country, it is necessary that forty-eight hours elapse before the deceased be interred, the body, therefore remained exposed in the chamber. Towards the middle of the second day, the sister of the deceased, in order to remedy the unpleasant odour, sprinkled the corpse with an aromatic fluid, when the body was perceived to move, and the coffin creaked. Dr. Schmitsmuller, a friend of the dead alive, was summoned, and, after resorting to the various resources of art, the patient was restored.

Introduction of a Foreign Body into the Rectum.

The following curious circumstance lately occurred at Vienna. A young man, hoping to relieve himself from the effects of an obstinate constipation, introduced into his rectum a hooked piece of wood, the long branch of which measures five inches, and the short one three and a half, a space of two inches intervened between their free extremities. In endeavouring to extract the fecal matter, great pain was occasioned; he then endeavoured to withdraw it, but failing in his attempts, he introduced it still further, hoping that it would undergo digestion. After the lapse of three weeks a surgeon was consulted, who found that by introducing his finger he could just touch the extremity of the long branch. After the administration of an enema he gradually introduced his hand, and with some difficulty grasping the piece of wood, he withdrew it entire, thus constituting a novel case of delivery.—*Gazette des Hôpitaux, Jan. 22.*

Physiology of Man in a state of Mental Aberration.

BY DR. SCIPIO PINEL.

A valuable and interesting work has been lately published by M. S. Pinel, "La Physiologie de l'Homme Aliéné." It evinces profound research, and furnishes the most important novel indications for the treatment of insanity, to be substituted for those commonly resorted to.—*Op. Cit.*

Curative virtues of Cold Water.

The celebrated Professor of Anspach, known by his writings on the medicinal virtues of cold water, has opened a school in that town

for the promulgation of his system; there are already a number of students.—*Gazette Medicale, Jan. 24.*

Observations on Fractures of the Clavicle and the Neck of the Femur.

BY M. GERDY.

In the majority of fractures of the clavicle, we know that the shoulder is carried downwards, inwards, and forwards. The depression arises merely from the weight of the limb, when the fracture takes place at the junction of the external with the middle third of the bone, for an equilibrium of power exists between the deltoïdes and trapezius; but if it occur more internally, the action of the deltoïdes is augmented by that of the pectoralis major in the depression of the external portion of the clavicle. M. Gerdy also considers a certain degree of elevation of the internal portion of fractured clavicle to be accomplished by the almost perpendicular action of the sterno-cleido-mastoïdeus, rendering it requisite to raise the shoulder above its natural level, in order to reduce the fracture. The sinking of the shoulder inwards is easily accounted for. The anterior protrusion, M. Gerdy considers, is greatly favoured if the patient lies on his back in a soft bed, into which the body sinks, while the shoulders, especially the one deprived of its support, are brought forwards. This is an ingenious hypothesis, but it does not embrace all the bearings of the case, for the shoulder is thrown forwards in the erect posture; and we have also a fourth change in position, consisting in a kind of twisting of the external fragment, well pointed out in the excellent treatise of M. Grout.

In refutation of the assertion that it is impossible to lift the hand to the head, he cites two cases of recent fracture, and another old and unconsolidated in a gendarme, which, however, did not in the slightest degree prevent the performance of his various duties. Bichat was, therefore, wrong in considering the clavicle of such great importance with reference to the motion of the superior extremity, and in saying that fractures of this bone reduce man to the level of non-claviculated animals, there is some want of exactness, for many of them have very great freedom of motion in the thoracic extremities, as bears, dogs, and cats which last yield to monkeys neither in address nor dexterity.

The pain caused by the elevation and abduction of the arm, as in raising it to the head, arises from a tendency to carry the shoulder inwards, which occasions the riding of the bone, and consequently the pain, which is, therefore, a prominent feature in these fractures; but also a similar effect may be produced temporarily by a number of other lesions, some of them of minor importance. Two cases of this kind occurred to M. Gerdy, in which there was no appreciable lesion. This sign, therefore, regarded by some authors as

pathognomonic, he looks upon as essentially dependent on pain.

Of the fracture said to be external to the coraco-clavicular ligament, but which in truth must take place in some part of the extent of its insertion, which is continued as far as the articulation with the acromion, M. Gerdy mentions one case. The displacement is of course very slight. The indications of this fracture are evident, but they have hitherto been successfully fulfilled by our apparatus. M. Gerdy suggests, that keeping back the shoulder by means of Brasdor's corset, separating the arm from the trunk by the interposition of a cushion, supporting and drawing the elbow inwards by means of a sling, combined with the use of a rather hard and convex bed, might remove the difficulty. A slight deformity, he considers, may remain, but without impeding the motions of the shoulder joint; nor ought the pain, in many instances, continuing for some time after consolidation, to be attributed to the rough surface of the callus, but to the violent bruise the bone has received. M. Gerdy has seen it occur in fractures the most perfectly reduced, and even in consequence of other physical lesions from external violence.

Fractures of the neck of the femur, besides the causes which act directly, appear to result from two very different mechanical actions. In that arising from a fall on the great trochanter, there is a tendency on the part of the neck of the femur to recover itself; in the other, which is more rare, taking place from a fall on the knee or the foot, there is a tendency in the angle formed by the union of the neck of the femur with the shaft to become more obtuse.

The diagnosis of this fracture is often of the greatest difficulty. M. Gerdy has pointed out a new sign, which gives it a greater degree of certainty. The patient reclining on his back, with the limb extended and rotated outwards, the extremity of the foot may be carried slightly backwards, which is seldom the case where there is a simple contusion of the hip.

M. Gerdy considers that it is possible to confound the fracture in question with other lesions, even under the existence of shortening of the limb, and rotation outward. In support of this opinion he relates a case, which left him some time in doubt, from the circumstance that shortening to the extent of three inches appeared too considerable. But the only dislocation in which rotation outwards takes place, is the one which is inwards and upward on to the pubis, clearly indicated by the protrusion of the head, which indication M. Gerdy does not appear to have attended to. The fracture of the femoral neck is much more closely simulated by certain fractures of the pelvis, in which, it is true, the limb is usually turned inwards, but this may occur in the first case; and again, there may be rotation outwards, as happened in one case observed by M. Gerdy.

With regard to treatment, he prefers continued extension, by means of Boyer's apparatus, in cases where the shortening is considerable, but where it is slight and easily overcome he makes use of demi flexion.

M. Gerdy terminates his work by the relation of a case of fracture of the neck of the femur by a gun-shot wound, accompanied by hæmorrhage. The femoral artery was tied, and the limb placed in Boyer's extension apparatus. At the end of four months there was a shortening to the extent of an inch and a half, which at the end of a month had increased to nearly three inches. The femur became firmly united to the ilium, and the limb could never be of great use, but the recovery from so severe a wound was highly satisfactory, and tends to the confirmation of the idea, that fracture of the neck of the femur from a gun-shot wound, is less important than that of the shaft of the bone itself.—*Op. cit.*

Foreign Hospital Report.

HÔTEL DIEU.

UNDER MESSIEURS RECAMIER AND TROUSSEAU.

Tracheotomy for Œdema and Ulceration of the Glottis occurring in an Adult—Death during the operation.

A PORTER, 52 years of age, of large stature, but thin, in other respects of a good constitution, was admitted into the hospital in November, 1834. He said that during the last thirteen months his voice had gradually altered, becoming more and more hoarse, and is now almost inaudible. Respiration has become difficult, the expiration requiring the exertion of the diaphragm. Incessant orthopnoea, awaking suddenly from sleep, and dysphagia became so aggravated, that the patient could no longer lie down, or swallow anything but a small quantity of broth, and that with the greatest pain. An enormous swelling is perceptible at the superior opening of the larynx, and pain is caused by pressure in the region of the os hyoides. There is cough, but no expectoration, nor is any pulmonary lesion indicated by percussion or the stethoscope.

This man having formerly been affected with the venereal disease, an antisiphilitic treatment was adopted, during which the symptoms appeared somewhat to abate at first, but soon reappeared with so much violence, as to give rise to such imminent danger of asphyxia, that tracheotomy appeared to be the only available resource.

On being informed of his danger, the unfortunate man expressed the greatest anxiety for the necessary operation to be immediately performed, declaring that he should die suffocated unless he was enabled to breathe. From the urgency of the symptoms and the anxious wishes of the patient, M. Trousseau resolved on the operation, nor did the courage of the patient flag in the slightest degree.

The skin was hardly divided, nor was a drop of blood shed, when syncope and convulsive motions supervened. On coming to himself in a few minutes the operation was resumed, but the syncope and convulsive movements returned, respiration also appeared to cease. The patient was then conveyed to his bed, and the trachea quickly opened; syncope continued; the blood from the thyroid veins dribbled into the air passages, without any expiratory effort to relieve them but the spasms of agony. The body was placed on the side to favour regurgitation, and by suction through a canula the blood was withdrawn, but death had claimed his victim.

At the post-mortem examination, great tumefaction of the epiglottis was found to exist; the lips of the glottis were the seat of numerous deep ulcerations, and a scirrhous and œdematous swelling, the opening they surrounded being nearly closed. The tumefaction had also extended to the termination of the pharynx and the commencement of the œsophagus; tubercles, not, however, in a state of softness, were discovered in the lungs.

It is important to ascertain the causes of this deplorable case. That tracheotomy was absolutely necessary is indubitable. Had the access of the air been rendered possible, all immediate peril would have been removed, and the topical application of remedial agents would have been rendered available; though the pulmonary tubercles might perhaps have progressed more rapidly after the operation, yet by it some months or even years of life might have been secured, and the purposes of art would have been accomplished.

The operator has to reproach himself with having performed the operation on the patient in the erect posture, from its predisposing powerfully to syncope, although the example of the greatest surgeons and the resolution of the patient will excuse it to a certain extent. Surely the occurrence of syncope and convulsions should have been regarded as a warning. There can be no doubt that the operation should have been adjourned, and reassumed under less disadvantageous circumstances. The records of medicine contain but too many examples of individuals of so peculiar a moral constitution, that the sight of the instrument alone has brought on profound syncope, or have sunk during an operation without hæmorrhage occurring, excessive pain, or the lesion of any essential part. The surgeon should look on such individuals as a kind of *noli me tangere*, and though it be impossible to ascertain this previously, surely on the first proof of it the surgeon should suspend all further attempts, both in accordance with the rules of art and the dictates of prudence, whilst the patient is under the influence of this insidious fatality.

The lipothymic tendency must have been greatly favoured by the state of inanition to which this person, otherwise in good health, was reduced. A similar syncope would, per-

haps, in a different operation, have been of but little importance, but in this case the flow of a small quantity of blood into the trachea became a cause of death, which was rendered far more powerful from lipothymia already menacing life. Nothing but the collapse was wanting to prevent the effusion of blood into the bronchii giving rise to expulsive efforts, for in twenty operations for tracheotomy on young and feeble infants labouring under croup, I have never seen the slightest accident result from the escape of a large quantity of blood into the trachea; it was energetically expelled as soon as it had entered. In the case under consideration, syncope prevented any reaction against the cause of asphyxia, and the patient sunk from the reunion of the two conditions, the first of which alone proved fatal, whilst the second could only be so from the accidental swooning of the patient.

If, when the veins began to bleed before the incision into the trachea, a sponge had been carefully applied to the divided vessels, less blood would have been effused into the air passages, and the patient might have borne up against it. This precaution was not taken till too late.

The operation itself in a thin individual is so devoid of difficulty, as to offer no reason for its fatal result.

British Hospital Report.

WESTMINSTER HOSPITAL.

Concussion.—REBECCA TURNER, æt. 20, admitted into Anne's Ward, September 26th, 1833, under Mr. White; is of the leucopneumatic temperament.

On the previous night a shelf of heavy books fell down as she was passing and knocked her down, she falling and striking the left side of the head against the iron door of an oven. She was stunned at the time, but recovered from the shock, and a surgeon saw her in an hour and a half; he found a small, nearly triangular wound at the top of the left parietal bone, which he examined, and came to the conclusion that the cranium was fractured. He sent her to bed, bled her twice, and purged her freely. The next day he sent her to the hospital when her head was immediately shaved, and the wound was found to have nearly closed; there was some slight tumefaction at the part, and a feeling as if there were some irregularity of the bone, but no depression could be detected; the pupils were natural, and the breathing not stertorous; pulse moderately full, and rather slow; sensible only at times; body cool; no heat of scalp; can put out the tongue when desired; it is furred; gives indications of great pain in the head. Ordered cold lotions and purgatives; rest and starvation.

7, P.M. Some short time after the cold lotions were applied, she spoke sensibly, and was able to answer questions; she is now sleeping quietly.

27th. Passed a tolerable night, and is now perfectly sensible, and nearly free from pain; the bowels have acted well; the pupils are natural, and act freely; no numbness or paralytic affection of any part; pulse regular; skin cool. Empl. lytta nucleæ.

28th. Is much better; free from pain, except from the blister, which has drawn well; pulse good; bowels open.

29th. Continues to improve.

Oct. 1st. Discharged.

On Wednesday, in the Court of Common Pleas, a novel action was tried. It was brought by a blacksmith named Hawke, against Mr. Hooper, a surgeon in the London Road. The plaintiff, complaining of a dizziness in the head, went to Mr. Hooper, and had about 24 ounces of blood taken from him. It was maintained that the operation was unskilfully performed, and that the plaintiff having for some time after been unable to go to his work was entitled to damages. Mr. Aston Key and Mr. Callaway of Guy's Hospital, and Mr. Wm. Cooper, gave evidence, to the effect (as we find it reported in the daily papers) that certain pains described by the plaintiff might arise from an imperfect division of certain filaments of its nerves, so minute that they could not be seen, and which sometimes come over that part of the veins to which the lancet is usually applied, and sometimes did not. The jury found for the defendant.

ROYAL COLLEGE OF SURGEONS.

NAMES of Gentlemen who received Diplomas during the month of January 1835.—Isaac Flower, Codford-St.-Peters, Wilts; Jas. Cunningham, E.I.; John Symons Longdon, London; Decimus Hands, London; John Hodgson, Chepstow; Alfred Hall, London; Henry Drew, Bath; John C. K. Coates, Salisbury; Robt. Howard, Dean-street, Southwark; Mark Brown Garrett, Shaftesbury; John Spencer Birch, Blackburn; Wm. Augustus Watford, Speldhurst-street, St. Pancras; Louis James Lovekin, E.I.; Robt. Dade, London; Henry Taylor, Oxford; James King Walter, Devonshire; Fred. Shury, London; Walter Duke, Hastings; Prior Purvis, Greenwich; Henry Affrel Snowdon, Ramsgate; Albert Philip Owen, Tenterden; Nathaniel Millard, Haverfordwest; Frederick Palmer, Yarmouth; Wm. Foxton Haley, Moulton, Spalding; William Reidy, Kerry; Francis Wyley, Higham, Stafford.

APOTHECARIES' HALL.

NAMES of gentlemen to whom the Court of Examiners granted certificates of qualification on Thursday, the 29th of January, 1835:—James Clark, Hoxton Town; John Drury, —; J. Ash Kirkpatrick, Clithero; John Spencer Birch, Blackburn; William Kennard, London; Benjamin Newbury, Cheltenham; Edwin Smith, Cirencester.

APPOINTMENTS.

Naval.—Mr. W. Gunn, assistant-surgeon, late of the Isis, to be surgeon. Mr. Thomas Miller, surgeon of the Dublin. Mr. John Pillmore, assistant surgeon, to do duty at Haslar Hospital. Mr. J. Aighton, assistant-surgeon to the San Josef.

General.—Mr. Henry Rush, of Henrietta-street, Brunswick-sq., Lecturer on Comparative Anatomy at the Westminster School of Medicine. Mr. Sharpe, surgeon to the Leeds Lying-In-Hospital.

DEATHS.

Mr. James Riddlesdon, of Ashbourn, Derbyshire, surgeon. Richard Saumarez, Esq., F.R.S., who in early life had an extensive practice in London, and who published some works on Physiology and Medical Science. Near Quebec, Pierre de Sulis Laterriere, M.D., formerly of Upper Tooting, Surrey. Surgeon Sheils, of the East India ship Amelia. Mr. P. Dickson, of Newington, Surrey, surgeon. Mr. Davenport, of Eastwood, Nottinghamshire, surgeon. Mr. Joseph Sunderland, of Halifax, surgeon to the Dispensary there. Mr. James Apner, surgeon, of Ilfracombe. Mr. F. T. Doolan, of Coley, Somersetshire, surgeon.

MISCELLANY OF FACTS.

It is reported that Mr. Battley has communicated his formula for the preparation of the liq. opii sedativus to the Royal College of Physicians for publication in the new edition of the Pharmacopœia. Query,—Had Mr. Home's discovery any effect on Mr. B.?

We feel pleasure in recording the following

magnificent bequests:—The Duke of Northumberland has presented the sum of £100 to the support of the Newcastle Anatomical Museum just established. The Marquis of Breadalbane, in addition to the bequest by his late father, has given £400 in aid of the fund now raising for the erection and support of an Infirmary at Perth, to be paid by instalments of £100 per annum.

LECTURES

INTRODUCTORY TO THE COURSE OF THE
INSTITUTES OF MEDICINE,

DELIVERED BY

ROBERT J. GRAVES, M.D.,

King's Professor, Dublin.

LECTURE X.

GENTLEMEN,—At our last meeting we spoke of the influence of poverty and want in augmenting the mortality of any particular community; on referring to what was then said, I find a few additional observations necessary, in order to prevent misconception as to the connexion between epidemic fever and seasons of want. It is by no means my intention to assert that fever cannot become epidemic, except in years of scarcity. Such a statement would be contrary to the truth, for it often happens that typhus is very general, both in Dublin and the provinces, when not the least dearth exists. Thus at the present moment (January, 1835), spotted fever is very common, both amongst the poor and the rich, although all sorts of provisions are very abundant. The same inappreciable atmospheric variations which occasion changes in the quality and type of fever, rendering it one year gastric, another cerebral, one season inflammatory, another nervous, are also sufficient to make it liable to great changes in its quantity and facility of diffusion. Indeed it is usual, as might, *à priori*, have appeared probable, to find a change in the quality of fever accompanied by a change in its quantity. Thus the moment the present fever assumed the type it now wears (which it did suddenly about three weeks ago), it at once began to diffuse itself extensively, arising spontaneously in many who were exposed to cold, and the operation of the usual causes of febrile action, and in others produced most evidently by contagion. Of the pupils attending the fever wards of the Meath Hospital, six sickened in one week, besides many patients admitted labouring under other diseases, and several nurses. If

however, in addition to the atmospheric causes now in operation, we had scarcity of provisions, and a state of unusual suffering among the poor, there can be no doubt that these circumstances would powerfully contribute to increase the spread of typhus in consequence of their rendering, by their combined effects on the body and mind, the great mass of the lower orders more predisposed to sicken, whether from atmospheric influence or from contagion. Having made these explanatory observations, let us return to our subject.

With respect to the chances of life, a few words will be sufficient. It may be worth while retaining in memory as a general fact connected with this matter, that, of a given number of children born in this country, one-third die before one year, one-half before the eighth year, two-thirds before the thirty-eighth, and three-fourths before the fiftieth year. You will, of course, understand that this calculation only applies to large numbers, for where the numbers are small, the results may be very different. Thus, on Patrick's day, in the year 1782, nine students walked from Trinity College, Dublin, to Bullock, where they dined. In 1833 eight of them were still alive, and I have not heard of the death of any of them up to the present period. I mentioned this fact the other day to a very fine old gentleman aged seventy-six, and he observed that he could communicate another of an opposite description. He said that he had served in the Irish volunteers in 1782, and that of his entire grenadier company, consisting of fifty men, there was only one now living. What a different fate overhung these two groups of persons. It is remarkable how long a certain set of men holding the same office sometimes happen to live in succession. There can be little doubt that the steady policy of the imperial court at Vienna has been partly, at least, owing to the extraordinary length of time the modern prime ministers of Austria, including Metternich, have lived. A similar successive longevity on the part of the rulers of Prussia, has aided other circumstances in aggrandising their territories, as has been well remarked by a late writer in the *Edinburgh Review*.

Some gentlemen who have heard me say so much respecting the chances of life, are anxious to have a short method of making an approximate calculation. The simple rule is, that the chances are equal that every healthy adult will live half the difference between his own life and eighty-one. This, which is the mode of computation generally employed, is very near the truth. Thus, if a man be forty years of age, the chances are equal that he will live half the difference between it and eighty-one years, viz. twenty years and a half, and, therefore, that the duration of his whole life will be about sixty years.

Having said so much respecting longevity, there are a few other points which remain to be noticed, as being connected with the general physiology of man. It is a remarkable fact that although there is no uniform proportion between the number of males and females produced by the same parent, yet that the total number of each sex brought into the world, taking the average of any large community, is nearly the same; or, to speak more exactly, that we have in all cases a small excess of males. The data that we possess, however, while they prove that this excess exists in all countries, seems to show that the amount differs in different places. Any person who takes the trouble of putting down the number of children in each family of his acquaintance, would find that in some there is a preponderance of males, in others of females, but when he came to arrange the whole under their respective sexes, he would be surprised to find their numbers so nearly equal*.

From a very extensive examination, it appears that in Germany and England the proportion of males to females is as twenty-one to twenty, while in Ireland it is generally as twenty-one to nineteen. Thus it appears that we have an additional Irishman out of every twenty-one born to have his head broken, at least, if the hypothesis be correct, which accounts for this greater proportion of males by supposing that Nature provided for their being destroyed in single combat or in war!

The necessity of this excess of males has been differently accounted for; but it would appear best explained, by supposing it for the purpose of providing for the greater mortality of the male sex before puberty. There is something in their constitutions which renders them more liable to fall victims to the diseases of infancy and childhood than those of the opposite sex; so that, after the period of puberty, the females slightly exceed the males in point of number. Thus, although the proportion of boys born is greater than the proportion of girls, the greater mortality among the former during childhood not only restores

the balance, but even causes a slight preponderance in the numbers of the latter, and this fact has been verified by making a comparative estimate of the adults of both sexes.

Some curious considerations claim our notice as connected with the proportion of males and females born, where the relative ages of the parents differ. An elderly man married to a young woman has generally the majority of his children boys, and *vice versâ*. "This," says Mr. Sadler, "compensates in some degree for the late marriage of the male, as otherwise such late marriages would consign a certain portion of the female sex to a necessary celibacy." Mr. Sadler also maintains, that early marriages are not more productive than late ones; that in the former case the mortality of the children is greater than in the latter, and therefore that they do not augment the population as much as they are generally believed to do. He has also endeavoured to show, that the marriages of the rich are not more productive than those of the poor, and that the increase of population is checked rather than otherwise by its density and degree of comfort. Certain it is, however, that many more women are barren among the rich than among the poor. Hence, it may be inferred (the discussion of this question is not within the province of the physiologist: I may, however, advert to it), that population will not be found to keep pace with the increasing wealth and comfort of the community. The richer people are, the fewer, it would appear, are their children; and, consequently, the elevation of the inhabitants of any country to a condition of increased comfort and independence, is not accompanied by a necessary tendency to an increased and superabundant population; and it is a fact, that population increases most slowly in those countries where the great bulk of the people are comfortable. I might instance that part of France, where the population does not double itself in the same time it quadruples in Ireland, Normandy, a province in which the peasantry are all small proprietors, and live in a state of comparative abundance.

With respect to the relation which the offspring bears to each parent, I shall beg leave to quote for you the following remarks, chiefly derived from Mr. Prichard's work:—Peculiarities in the progeny, or hereditary conformation, as it is termed, are generally supposed, and apparently with some ground, to be determined chiefly by the father; that is, the offspring follows principally the male parent, though it is liable to partake of the peculiarities of the mother. Children resemble in feature and constitution both parents, but I think more generally the father. In the breeding of horses, oxen, and swine, great attention is paid by experienced propagators to the males. In sheep, it has been commonly observed, that the black rams beget black lambs. In the human species, also, the complexion chiefly follows that of the father

* Born within the city of London and the bills of mortality, from Dec. 10, 1833, to Dec. 10, 1834—Males, 13,601; Females, 13,615.

and I believe it to be a general fact, that the offspring of a black father and a white mother is much darker than the progeny of a white father and a black mother. In the West Indies, the mixed offspring is descended from white men who cohabit with black women. In England, it often happens that black men who are brought from the West Indies as servants marry white women, while it is uncommon for black women to get husbands in England. The English Mulattos are consequently blacker than those born in the West Indies, who generally spring from the black concubines of white men. It seems indeed that, in some instances, the junction of a female of a certain species with a male of a peculiar character has had a further influence on the progeny of the former than any one would have expected; it has even influenced the character of several successive births. Thus a male quagga crossed a mare, and the mule resembled the quagga strongly. Two or three foals, which the same mare afterwards bore by stallions, had all more or less of the quagga marks! This fact concerning the quagga is very curious, and affords a faint analogy to what has been observed in certain genera of insects, where one impregnation fecundates not only the female actually in question, but several succeeding generations!

As far as the size or stature of the offspring is concerned, it seems to be pretty well ascertained by facts known to the breeders of cattle and horses, that this chiefly depends on the mother. Perhaps the sex of the offspring also is determined chiefly by circumstances connected with the mother. Some women seem to be prone to produce a great proportion of male, others of female, children; and I think these peculiarities are common among the females of particular families.

With regard to the relative number of males and females born from a given number of marriages in different ranks of life, it has been found that, though the aggregate number of each sex is nearly equal when we take the whole community, yet there is a difference in the number of each sex among the different classes into which that community is divided. Some interesting observations on this point have been made by M. Giron. He divides individuals into different classes; the first is composed of individuals whose employments tend to develop their bodily powers; the second, of those whose business tends to enervate; the third, of those whose employments are of a mixed description. He found that, in the first class, the number of male births exceeded the average proportion of male and female births throughout France; that, in the second class, the number of female births exceeded the average proportion of female to male births throughout France; and that, in the third class, the proportion of male and female births was nearly the same as the average proportion throughout France. Hence

he arrives at the conclusion, that the pursuits of agriculture tend to the increase of the male population, and that the habits of commerce and manufactures favour an augmentation of the female population.

In addition to what has been already said, let me make a few cursory observations on the variety in the proportion of births to a marriage. It has been supposed that the fecundity of marriages is in proportion to the comfort and independence of the community, and that fewer children are born from a given number of marriages in countries which are deficient in agriculture, industry, and the blessings of civil liberty. This, however, is not the fact. In England the proportion of births to marriages from 1800 to 1810, was as 4 to 1, and from 1810 to 1821, as 4·22 to 1. In Scotland and Holland it is as 4·2 and 4·20, while in Russia and several of the Italian states it is as 5·25 and 5·45, to 1. I shall not take up your time with these statistical details any farther than to observe, that in the degree in which a nation advances in prosperity and civilisation, premature and imprudent marriages will become less frequent, and the number of births be proportionally diminished. The lateness of marriages may be generally taken as a good test of an improved state of society, as exhibiting that power of moral restraint over his passions which should characterise civilised and intelligent man.

I had almost forgotten to mention the remarkable fact, that the cultivation of science and literature appears to be favourable to longevity, contrary to the opinion generally entertained on this point; indeed it seems that the man who is chiefly engaged in mental labour has a fairer prospect of length of years than he whose occupations consist in exclusive bodily toil. Franchini has enumerated one hundred and four Italian mathematicians of different epochs; he has ascertained the ages at which seventy of these died, and among them we find eighteen who had attained the age of eighty, and two of ninety, and this in a climate which is not generally considered to be favourable to longevity. In France, one hundred and fifty-two men of science and letters have been taken at random; half the number appears to have cultivated science, and about half to have devoted themselves to general literature; on adding together the age at which each of them had died, it was found that the average result would be above sixty-nine years, for each individual*.

* This average duration of the lives of literary men which is given by Hawkins, is evidently greater than can be allowed, neither are Madden's tables of the mean duration of the lives of *literati* free from the same error, as is well shown in the *Quarterly*.

Comparative Longevity of Female Authors of the last Century.—*Quarterly Review, No. 99, on Madden's Infirmities of Genius* *.

	Age		Age
Lady Russell	. 87	Mrs. Chapone	. 75
Mrs. Rowe	. 63	Mrs. Lennox	. 84
Lady M. W. Montague	. 73	Mrs. Trimmer	. 69
Mrs. Centlivre	. 44	Mrs. Hamilton	. 65
Lady Hervey	. 70	Mrs. Radcliffe	. 60
Lady Suffolk	. 79	Mrs. Barbauld	. 83

Mrs. Cowley	. 66	Mrs. Inchbald	. 68
Mrs. Macaulay	. 53	Mrs. Piozzi	. 80
Mrs. Montagu	. 81	Mrs. H. More	. 89

I may repeat here what I have already mentioned, that in England there is a remarkable difference between the mean duration of life in the agricultural and manufacturing districts, a fact which goes to prove that the mode of life, and the various physical circumstances connected with the different pursuits and occupations of men, have more influence than the mere effects of climate. Indeed it is one of the evils of civilisation that it forces a nation to earn wealth by the too often debilitating employments of manufacturing industry. However great and powerful in a commercial or political point of view manufactures may render a nation, it is established beyond all doubt, that the combining of people into large masses, which the perfection of manufacturing arrangements requires, has a strong tendency to spoil the race. Go into Manchester, or any of the large manufacturing towns, where men, women, and delicate children, are confined for ten, twelve, and fourteen hours to the heated and unwholesome air of a factory, and consider for a moment what the result of such a mode of life must naturally be, and what effects it must produce on the physical qualities of the race. Could you expect that a mode of life such as this, continued for several generations, should have any other effect than giving rise to a race of men characterised by degenerated stature, impaired energies, and premature decrepitude? Formerly few large cities were able to maintain their own population; the number of deaths exceeded the births, and they would have dwindled away, in point of inhabitants, had they not received from time to time a fresh supply from the country. This, however, is not the case at present. The numerous and important improvements in ventilation, watering, and other matters of police, as well as the more general diffusion of the comforts of life, and the more successful treatment of disease, enable our large cities to maintain their own population and even to increase it.

Some cities, however, seem, from the opera-

tion of unfavourable causes, incapable of supporting their own population; they are, however, very few in number, and it is probable that as the arts of life and the blessings of civilisation become more diffused, their number will be still further diminished. The principal, and I believe the only ones of this description at present, are Rome, Petersburg, and Stockholm; in these cities the number of deaths exceeds that of births. What the cause of the preponderance of deaths over births in Rome may be I have not been able to ascertain exactly, there is, however, a remarkable difference, the births being one in thirty, the deaths one in twenty-four. At St. Petersburg, in the year 1833, the births were 9,311, the deaths 17,085. It is to be observed, that at St. Petersburg the males exceed the females by nearly 100,000, owing to the great influx of servants and persons depending on the court. Modern improvements tend to remedy this loss in some degree; still it appears from the investigations of Mr. Robertson, that the greater mortality of children as well as of adults in all large towns opposes a very material obstacle to the increase of their population, particularly when combined with other causes unfavourable to reproduction and longevity.

A very curious subject for investigation has been lately brought forward in France and this country, namely, the supposed influence of season and atmosphere on the commission of crimes. The inferences which have been made with respect to this very singular question are by no means established, and I mention the circumstance *en passant* to excite your curiosity, in order that you may investigate it when opportunity offers. It has been stated that man is so much under the influence of physical causes, that the quantity of crime committed in any great mass of society varies with the seasons, that each season brings back a recurrence of the same crimes, and, even as to minutiae, almost exactly in the same proportions. This fact seems to be explicable by the varying wants, varying opportunities, and perhaps (but I much doubt this) by the physical influence of the seasons on the bodies of criminals. It has been however stated, that the temperature of the air, the quantity of moisture or drought, the various electrical conditions of the atmosphere, &c., influence our bodies, and through them react on our minds, and that this concurring with immoral influences renders us less capable of resisting the tendency to commit crimes of a particular description. It has been also asserted that these crimes vary with the season of the year, the offences against property being most common in winter and spring, those against life in summer and autumn. It is quite plain that this may be considered in various points of view. Thus we can easily conceive that the long winter nights will give a facility to the operations of

* N.B.—This table is not Madden's, but is given by the Reviewer.

the thief and robber which they do not enjoy in summer, and therefore it is natural to expect that offences against property will be more numerous in the winter season.

While on this subject I may observe, that there are a great number of curious facts with regard to one of the greatest of crimes, suicide. If we look here for the influence of season, it would appear that the greater number of suicides occur in summer. Thus, in that part of London, called the City of Westminster, the average for many years shows that the number of suicides in November is one-third less than in June. In France, also, November, December, January, and February fall greatly below the other months of the year as to the proportion of suicides. With regard to this crime it is strange but nevertheless true, that where moral and religious education is neglected the number of persons who kill themselves is increased in proportion to the extent of civilisation.

Among the capital cities in Europe, Dublin and Naples are those in which the fewest suicides occur; on the other hand, Paris and Berlin are remarkable for the number of persons who destroy themselves. In Spain the proportion is very small, and the same thing may be said of many other nations both in the old and new world. From the habit our English neighbours have of publishing every occurrence in the newspapers, they have earned for themselves the reputation of being the most suicidal nation in Europe. English spleen and English suicides are a common topic of conversation on the Continent, and it is believed that the combined effects of fog, spleen, and a melancholic temperament, prove so irksome to John Bull, that he makes away with himself in despair. This, however, is a false supposition. Later and more accurate returns have proved, that the English are not half so prone to self-destruction as their more mercurial French neighbours, and it is probable that there are five times as many suicides annually in Paris as there are in London. In Paris they wisely conceal those things from the public, in London they publish every thing. Murders, suicides, and other revolting crimes are detailed in the newspapers with an elaborate and disgusting minuteness, and pictures of human guilt in all the glaring deformity of circumstantial detail and heightened colouring are exhibited day after day to gratify the morbid taste of a prurient and culpable curiosity. I need not tell you, gentlemen, that this is unwise, unphilosophical, and pernicious in its effects. There is a principle of imitation in the human breast, deeply blended with our natures, and given for a good purpose, though it is but too often perverted. It prompts us to imitate what is great, noble, and useful, but sometimes it inclines us to copy what is bad, and there can be no doubt that murders and suicides have been committed by hearing or reading accounts of them in the public prints. It is not that the mind of the reader is captivated by the

account of a murder or suicide. But men of weak minds will sometimes, on reading a vivid description of self-destruction, get a strong and fixed idea into their heads, this idea becomes daily more and more impressed on the mind, so that they can think of nothing else, and when we add to this fixedness of idea the ordinary tendency of thought which is to impel to action, we arrive at an explanation of the fact, that the propensity to commit suicide may and does sometimes originate in imitation. Thus, after the death of the late Lord Castlereagh, it was remarked that several persons destroyed themselves in the same way. For the same reason it appears injudicious to give too particular and circumstantial details concerning the last illness and death of persons who have been objects of great public interest. The impression thus made on the minds of persons, who either are, or believe themselves to be, similarly affected, often leads to the worst effects, as was exemplified by the great mortality among lying-in ladies which was observed after the death of the Princess Charlotte. A very remarkable case of this description occurred while I was at Hamburg. My friend, Dr. Oppenheim, was called out one day to visit a man, who had cut his throat. The carotids escaped, but the injury inflicted was so great that the patient died after protracted sufferings. His body was given to Dr. Oppenheim for dissection. The man, who took care of the place, happened to be in the room at the time, and Dr. Oppenheim said to him in a joking way, "John, have you any fancy to cut your throat? If you have, don't do it in such a bungling way as this man, a little more to the left here and you will cut the carotid artery." The individual, to whom this observation was made, was a very sober steady man, with a family and a comfortable subsistence, he never manifested the slightest tendency to suicide, and had no motive to commit it. Yet strange to say, the sight of the corpse of a suicide, and an observation uttered in jest, made a powerful impression on him; the idea of self-destruction seized upon his mind, and about an hour after Dr. Oppenheim left the dissecting room he was horrified at hearing that John had cut his throat. Fortunately he had not profited by the anatomical instructions given to him, he did not cut the carotid, and consequently recovered.

Most of you, I believe, remember the extraordinary history of suicides at the *Hôtel des Invalides* at Paris. In this institution there was a long dark corridor, with a projecting beam, or post, at the darker end of it. It was a place well adapted for the purposes of suicide, and accordingly one of the pensioners came there one day and hanged himself. In the course of a few days six or seven others did the same. This caused an extraordinary sensation; the like had never been heard of before; the inmates were comfortable and happy, and the crime of self-destruction almost unknown among them. The post was removed, and a window broken open at the end of the

corridor, the peculiar associations of the place were thus dissipated, and there were no more suicides.

I could bring forward many other facts to show that the propensity to commit suicide is encouraged, not only by imitation but also by other causes. It would appear, that industrious and prudent people, who have a regard for their families and are anxious to provide for them, very seldom commit suicide. Accordingly we find, that, out of 120,000, who insured their lives in the Equitable Insurance Office, the number of suicides in twenty years was only fifteen.

The causes of suicide are frequently difficult of explanation. It has been attributed to climate, temperament, education, political and private condition, and many other circumstances. It is a curious fact, that the Irish are the least suicidal nation in Europe. The two cities, in which the fewest suicides occur, are Dublin and Naples. And it is remarkable, that in both these cities the bulk of the population resemble each other very closely. Between our poor citizens and the Neapolitan Lazzaroni there are many points of resemblance; the same bodily vigour, the same patient endurance of hardship, the same buoyancy of spirits and quaint humour, the same carelessness of the future, and, I am sorry to add, the same poverty are remarkable in both. Still they never dream of self-destruction. An Irishman has sometimes very little compunction in knocking his better dressed neighbour on the head, but he never thinks of killing himself. We have forty murders for one committed in Prussia, and they have forty suicides for one committed in Ireland. This calculation I made about ten years ago, and it was the result of much investigation. Both nations have since materially changed. Fewer Prussians, in proportion, are now killed by themselves, and many more Irishmen are now killed by others*. This is a curious subject and well worthy of the attention of the philosopher and legislator.

With regard to the connexion between education and crime I shall be necessarily brief, as I am anxious to proceed to the subject of temperaments. In France, it appeared before the Court of Assize, in the year 1832, that of the accused 4,540 could neither read nor write, 2,192 could do so imperfectly, 682 could read and write well, and 151 were educated in a superior manner.

In speaking of longevity yesterday I forgot to mention a curious instance which occurred in my own family. The Rev. Dr. Graves, of Templemore, died the year before the last at the age of 84. During the years 1758 and 1759 he lived in the house of his great grandmother's brother, John Newell, who was high sheriff of the county of Limerick in 1712.

* If official statements are to be relied on, the increase of murders in Ireland has been progressive since the *penultimate* rebellion.

Mr. Newell lived at Anglesborough, on part of Lord Kingston's estate, in the county of Limerick. He was nearly 50 years old at the Battle of the Boyne, where he served in King William's army. He died about the year 1760, aged 127. In this instance I had an opportunity of witnessing how far back a few links in the chain of traditional testimony may occasionally carry us, as I have heard at my own table anecdotes of the Battle of the Boyne, told by a person who had heard them from one actually present at that battle.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XVIII.

Partus ante justum Terminum.

GENTLEMEN,—You will recollect that, when speaking of applying the ligature in cases of polypos uteri, I regretted not being able to show you the instrument, which has been lately invented by Baron Graefe, of Berlin, for this purpose. I here show it to you, and consider it one of the most elegant and perfect specimens of ligature apparatus which has ever been invented*.

I now come to the subject of *partus ante justum terminum*, or *premature expulsion of the fœtus*, a subject of great practical importance to the practitioner.

Although the natural term of utero-gestation be forty weeks, or ten lunar months, yet it not unfrequently happens that the uterus expels its contents long before the expiration of this period, hence the *partus ante justum terminum* requires to be considered before coming to the subject of natural labour. To simplify it as much as possible I shall divide it into three species, viz. *abortion*, *miscarriage*, and *premature labour*. Under the head of abortion have been classed all those cases of premature expulsion of the fœtus, which occur before the sixteenth week of pregnancy, after this period they are called miscarriages, and retain this denomination until the twenty-eighth week, or seventh lunar month, from which time until the end of pregnancy they receive the name of premature labours.

Although a fœtus may be born, and show distinct signs of life at a very early period, it

* It would be needless entering into a minute description of this beautiful little instrument without the necessary illustrations, more especially as Mr. Weiss, junior, has published a translation of the original paper, in which Graefe first described it, together with several engravings.

is nevertheless unable to prolong its existence, beyond a few hours, until the commencement of the last division, or, in other words, until the twenty-eighth week of pregnancy, after which time, although extremely delicate, it may, with care, be reared.

It is not less important to bear in mind the distinction between abortion and miscarriage than between miscarriage and premature labour, not so much with regard to the fœtus (for that can never be preserved if born during the two first divisions of premature expulsion), but in order that we may be better able to form a correct idea of the degree of danger to which the mother is exposed. *Abortion* is the most frequent, and fortunately also the least dangerous, form of premature expulsion of the fœtus; thus, for instance, Dr. Hamilton says, "women mostly miscarry between the eighth and twelfth weeks," and Carus observes, that "abortions are safest for the mother during the first eight weeks of pregnancy, on account of the inconsiderable development of the ovum, whereas, in the later months, they disturb the health much more." Nevertheless Smellie considers them as seldom dangerous before the fifth month of pregnancy, when they would come under the denomination of *miscarriages*. The liability to abortion is greater in the earlier than in the later stages of pregnancy, for, as the union between the decidua and chorion is not well confirmed, as the attachment of the decidua to the internal surface of the uterus is proportionately slight, and as the extent of surface, which the ovum now presents, is very small to that which it offers in the more advanced state of pregnancy, and as it can of course be affected by smaller causes, it will be seen that a separation will be more easily induced, and prove much more injurious to the well being of the embryo than a large one at another stage †.

The uterus may be excited to expel its contents before the proper term of pregnancy from many causes, it may arise from deficient nourishment of the fœtus, and thereby its death; this may be caused by local, febrile, and chronic diseases, debilitating evacuations, depressing passions of the mind, &c. You will recollect, gentlemen, I mentioned to you a variety of symptoms, which are said to denote the child's death in utero; a sudden shivering, general sensation of uneasiness, loss of appetite, bad taste in the mouth, sensation of weight and coldness in the abdomen, flaccidity of the breasts, relaxation of the portio vaginalis uteri, discharge of a fœtid blood-coloured mucus; but as I have already told you, when speaking of this subject at my last lecture, the chief symptom to be depended upon, is the sensation of the rolling about of some heavy body in the abdomen as the patient turns from side to side; the moment the fœtus ceases to exist it acts upon the uterus like any other

foreign body, and excites it to contract and induce expulsion; the interval, however, between the death and expulsion of the fœtus varies exceedingly; when small it does not produce much irritation, and may be retained in the uterus for some time, and my friend, Mr. Crosse, of Norwich, informed me of an interesting case, where the fœtus was not expelled until four months after its death; this, however, does not occur when the fœtus is older, and has attained a greater size, being then usually expelled much sooner, for, as Smellie observes, miscarriage ensues from the membranes, after the child's death, running gradually into putrefaction, and thus, not being able to bear the pressure of the uterus, they burst. Premature expulsion of the contents of the womb may arise from external violence, producing separation of part or the whole of the ovum from the uterus; thus we see it frequently caused by blows, falls, and violent exertions, by the patient lifting heavy weights, and otherwise straining herself; we frequently see it produced by attempts to reach any thing high above the head; thus, in the lower ranks, where the patient has tried to take any thing off a high shelf, or, in the upper classes, where she has endeavoured to dress her own hair; perhaps nothing will produce it sooner than the sudden and half involuntary start of the muscles in attempting to save herself from falling when she has stumbled or tripped, although she does not fall, or even strike herself against anything, still she will almost instantly feel aware of some injury having taken place in the uterus, from the sudden violent motion of the child, which, after a little time, will cease altogether, and also, in all probability, from the appearance of hæmorrhage.

It may also arise without the previous death of the child, from affections of the mind, as sudden fright, violent anger, or grief, &c. An inflammatory action in the lower part of the intestinal canal, more especially a dysenteric affection, or a similar state produced by the improper use of irritants and stimuli, such as savine, aloe, and other drastic purgatives, will also induce contractions of the uterus.

Premature expulsion of the ovum may arise from internal causes, and when this is the case, it mostly happens at what, in the unimpregnated state, would have been a menstrual period.

General plethora is a frequent predisposing cause of abortion, for, occurring in conjunction with the increased vascular action, which takes place at this time in the uterine system, it produces, as it were, an apoplectic state of the uterine sinuses which form the internal part of the placenta; hence hæmorrhage results: this, however, of itself, does not induce uterine contractions, but acts indirectly, by causing the child's death.

Spasmodic affections not unfrequently act as causes of abortion; thus, for instance, palpitation of the heart, which is occasionally troublesome in the earlier months, is apt to

* Dewees.

excite abortion *. Cough, if severe, will have the same effect. Violent toothach has been known to produce it. According to Mr. Burns, the gravid uterus at various periods is liable to be affected with spasm, by which the ovum is almost always expelled. But the most frequent cause of all, is the enjoyment of too much connubial intercourse during the first three months of pregnancy. In the latter half of pregnancy, this cause of course does not exist, although she remains as liable to the action of the other causes of abortion as before. It is a well-known fact, that abortion is much more frequent with females of high rank than those of the middling and lower classes. According to Professor Naegele's experience, one-fifth, or even a fourth, of women in high life suffer abortion during their first pregnancy; this is easily accounted for by the luxurious and inactive life they lead, from the use of indigestible and stimulant food, taken too largely in proportion to the quantity of exercise, from keeping late hours, tight dressing, &c. The same causes which, in the unimpregnated state, produce a faulty condition of the menstruation and other disorders of the uterine system, now act as so many causes of abortion.

The sudden cessation of the breeding symptoms, with sense of weight and coldness in the lower part of the belly, with flaccid breasts, pain in the back and loins, and discharge of blood from the uterus, are pretty sure signs of abortion; hence we may define abortion to be "separation of the ovum with contraction of the uterus." According to Mr. Burns, when the ovum has not descended into the uterus, hæmorrhage occurs without contraction of the uterus, and therefore without pain; in fact, merely the symptoms of menorrhagia. When, however, the ovum has acquired the size of a nut, contractions of the uterus with pain in the loins, and hæmorrhage, will follow. "*Where uterine pain precedes or accompanies the discharge, expulsion cannot be prevented, but where the discharge precedes the pain, if the child be alive, it frequently may* †." On the other hand, Puzos declares that neither pain nor hæmorrhage necessarily produce abortion.

* Burns.

† Burns. This fact has been confirmed by my friend Mr. Ingleby, of Birmingham, in a valuable paper entitled "Illustrations of Midwifery," and published in the *Dublin Medical Journal*, Jan. 1835.—"A protracted hæmorrhage," says this experienced practitioner, "may not necessarily destroy the fœtus, or terminate in abortion, notwithstanding the well-known tendency. As a striking illustration, a lady, whom I recently attended in her confinement, had an unceasing hæmorrhage during the first three months of pregnancy, and yet abortion did not happen, and she was delivered at the full term of a living child."

When a considerable separation takes place, as must be the case when it commences at the upper parts of the uterus, pain will more likely occur than when it happens near the neck; hence, we sometimes have pain before the blood issues externally. The uterus, in this instance, suffers irritation from partial distension, from the blood insinuating itself behind the ovum; contraction ensues; the blood is forced downwards, and is thus made to separate the attachment between the ovum and uterus in its course, until it finally gains an outlet at the os tinæ. In consequence of the uterus being excited to contraction, the friendly coagula which may have formed from time to time are driven away, and the bleeding each time is renewed, and accompanied most probably with increased separation of the ovum, until at length, from its extent, the ovum becomes almost an extraneous body, and is finally cast off; hence separation at or near the os uteri will not be so dangerous, and in all probability there will be hæmorrhage without pain, which is the contrary when it takes place near the fundus.

With regard to the *treatment*, gentlemen, you must be, in a great measure, guided by the constitution and strength of the individual. On the appearance of hæmorrhage, if the system be plethoric, venesection will be advisable, but in weakly habits it will be improper, for, as Mr. Burns observes, the fulness and strength of the pulse sink much sooner in abortion than by mere loss of blood. In every premature labour, especially in the first stage, we must prevent all exertion, refrain from stimulants, and preserve the horizontal posture. Rest is absolutely necessary; the patient should be kept in a state of perfect quiet both of body and mind; she should lie upon a hard mattress; her clothing should be light, and the air of the apartment kept as cool and fresh as possible. By a timely venesection, where there is plethora, much distress may be avoided, and, having premised this depletion, opiates will prove of the greatest service. In weakly habits, and in every instance where the hæmorrhage does not depend upon plethora, a full dose of laudanum will produce the happiest effects. The application of cloths dipped in cold water to the back and vulva, sponging the legs, arms, and even the trunk, are very beneficial: in the first attack this cooling plan is to be used in all its vigour, and we must not quit our patient for an instant *. Smellie, in cases of flooding, gave twenty drops of laudanum, and repeated five or ten more in half an hour, applying cloths dipped in vinegar to the pudenda. If the hæmorrhage become at all profuse, it is a sign that considerable separation of the placenta has been produced; and when this is the case, as we can have no reason to suppose that reunion will take place, all hopes of preventing ex-

* Burns.

pulsion must be relinquished, and our sole attention directed to assist the uterus in evacuating its contents. But, although this is the only means by which a certain as well as permanent cessation of the hæmorrhage can be obtained, there are several changes which must take place in the uterus before this process can be effected, requiring more or less time; the ovum must be completely separated from its attachments with the uterus, and the contractions of that organ must have been of sufficient strength and duration to produce such a dilatation of its mouth and neck as to allow the ovum to pass; but, before this can be effected, such a quantity of blood may have been lost as greatly to endanger the life of the patient. Hence we must use such means of treatment as will stop the hæmorrhage, and also give the os uteri time to dilate sufficiently. The most effectual means is the *tampon* or *plug*; this was recommended so long ago as 1752 by Dr. Smellie, since which it has been noticed and highly approved of in a valuable work on Uterine Hæmorrhage by M. Leroux, of Dijon. The application of it has been variously directed. Dr. Smellie recommends the vagina to be filled with tow or linen rag dipped in any cold astringent liquid, while Mr. Burns advises plugging the vagina with a large piece of linen dipped in oil, and says that he has enclosed a piece of ice in the plug with the best effects; but I prefer the tampon used by Dr. Dewees, of Philadelphia, which is merely a piece of soft sponge of sufficient size to fill the vagina; this should be wrung out of pretty sharp vinegar, and then introduced. Dr. Dewees considers that the sponge tampon promotes the coagulation of the blood more quickly than any substance hitherto employed, from its numerous cells quickly giving passage to the finer parts of the blood. The sponge is much more easily introduced into the vagina, and, when introduced, produces much less irritation than the plug recommended by Mr. Burns. If, however, the flooding has not been very alarming, the action of cold applied externally will generally be sufficient to induce such a degree of coagulation as to close the mouths of the bleeding vessels sufficiently until expulsion has taken place. In severe cases, as long as the os uteri is firm and unyielding, as long as it has no tendency to dilate, or the uterus itself to contract, we may safely trust to the plug, rest, and cold.

Dr. Dewees, in his valuable compendious System of Midwifery, has highly recommended the internal use of the acetate of lead, given in small and frequently repeated doses. "We know," says he, "that the acetate of lead sometimes produce the most decided effects, let the mode of its doing so be what it may; for, in many cases, it seems to exert a control over the bleeding vessels as prompt as the ergot of rye does upon the uterine fibre." If the patient has suffered much from hæmorrhage, if the action of the uterus be weak, we

must deliver, and this, after one or two attacks of syncope, is not difficult, for the uterus suffers dilatation, and the os uteri becomes dilatable; but this must not be considered as a rule, for syncope is dangerous, and must not be waited for. In such cases vomiting occurs, and may do mischief by displacing clots already formed. But it sometimes seems to excite contractions of the uterus, and give it a disposition to empty itself. In such cases, a cloth dipped in tinct. opii and camphorated spirits of wine, and applied to the epigastrium, will produce relief*. We should also be careful to examine the blood upon the napkins of the patient, for the ovum may be expelled and thrown away with the coagula without our being aware of it.

Where there is every reason to suppose that the ovum is nearly or entirely separated from its connexions with the uterus, and where the os uteri is very little dilated, more especially where a portion of the ovum or placenta protrudes at the os uteri, Dr. Dewees has used a small wire crotchet with very good effect. Levret, who was aware of the same difficulty, recommended its being left to nature, although at the same time he observes, that injections of tepid water sent up in a powerful stream into the vagina are often useful. The larger the body to be expelled is, the more powerfully and effectually does the uterus contract; hence we ought never in the first three or four months to pierce the membranes in hopes of accelerating the expulsion, for the very reverse happens: the waters run out, and the fœtus, after a continuation of the bleeding, at last escapes, but the placenta and membranes remain. From the diminution of bulk, the uterus cannot expel them so soon as if we had not interfered; the disease is therefore longer protracted, more blood is lost, and a greater injury done to the system than if the woman had been let alone. In the latter months of pregnancy, however, the case is different, for then the quantity of blood effused is sometimes such as to make it necessary to produce a diminished size of the uterus and its vessels. At this time the size of the fœtus keeps up the action of the uterus after the escape of the waters, and excites its own expulsion †. Nature appears to attend to this point in a very striking manner, for it is as rare to see the fœtus precede the exit of its involucri *before* the third month, as to see it come enveloped in them *after* the fourth. Burton has given a very instructive case of habitual abortion cured by the judicious use of the lancet, &c., for it shows how carefully you must attend to the constitution and habit of the individual, and how completely by this must your practice be modified. A woman, having miscarried seven times, sent for him to attend her under symptoms of threatened abortion, which shortly after took place. "She was a healthy but not robust woman, her complexion rather

* Burns.

† Ibid.

pale and fair, and her arteries small, with a feeble pulse even in her best state of health. Some time after this, she sent for me, not having had her menses at the usual time. Her pulse was then feeble, and she had not the usual uneasiness from the obstruction, or yet any symptoms that usually attended the eruption of the menses. About a week before the time the menses should appear again, she began to have complaints that used to precede their eruption, wherefore I ordered ℥vj. only of blood to be taken from the arm, and gave her a gentle opiate at night. This I repeated in six days, she still going on with the use of gentle corroborants and stomachics. The week before the third month I ordered about four or five more ounces of blood to be taken, and the third or fourth day after to take ℥iv. more, and again on the fourth day to be repeated, and each night after bleeding she took the opiate, so that in about nine days she lost from twelve to thirteen ounces of blood. The week before the fourth month she lost ℥iv. more from the arm, she still continuing the medicines as prescribed till she entered the sixth month of pregnancy without any other bleeding, and then went on to her full time, and brought forth a living child. After the first miscarriage she had been bled every time she was pregnant, but then they took ℥xij. at a time, without considering that her feeble pulse would not bear the loss of such a quantity."

With regard to *the prophylactic treatment*, a peculiar diet for a female during pregnancy is by no means necessary, nevertheless it behoves her to be upon her guard against any causes which may excite a disposition to abortion, hence she must carefully avoid every thing which may affect the circulation, as affections of the mind, heating food, violent exercise, constipation, and the various other causes which I have just enumerated. Nothing can be more mistaken than the notion of its being necessary to take an extra quantity of nourishment during pregnancy for the support of the child as well as of the mother. Nature contradicts it in the most striking manner, for by the nausea and sickness with which most women are troubled during the first half of their pregnancy, she raises an effectual obstacle to any error of this kind. "It certainly cannot be intended (says Dr. Dewees) for any other purpose, since it is not only almost universal, but highly important when it occurs, as it would seem to add much to the security of the fœtus, for it is a remark as familiar as it is well grounded, that very sick women rarely miscarry, while, on the contrary, women of very full habits are disposed to abortion, if exempt from this severe but, as it would seem, important process." If she has already had an abortion in a former pregnancy, these precautions should be enforced with double vigilance, for the uterus soon acquires, as it were, a habit of retaining its contents only to a certain period, and then pre-

maturely expelling them; when this is once the case, it becomes exceedingly difficult, and is often actually impossible, to make it carry the ovum to the full term of utero-gestation, and despite of the greatest care the symptoms of abortion will come on at nearly the same time at which they occurred in former pregnancies, and frequently to the very week. In such cases, if the patient be plethoric, she should use exercise, the cold bath, anti-phlogistic regimen, and occasional venesection.

"We might often prevent abortion," says Baudelocque, "if we were perfectly acquainted with its cause, even when the labour is already begun. A very plethoric woman felt the pains of childbirth towards the seventh month of her pregnancy, and the labour was very far advanced, when I was called to her assistance, since the os uteri was then larger than half-a-crown; two little bleedings restored a calm so much, that the next day the orifice in question was closed again, and the woman went the usual time. Food of easy digestion, prudently administered, quieted a labour not less advanced in another woman, where it was suspected to be the consequence of a total privation of every species of nourishment for several successive days; delivery did not take place till two months and a half afterwards, and at the full time; emollient glysters and a very gentle cathartic procured the same advantage to a third woman, in whom the labour pains came on between the fifth and seventh months of pregnancy after a colic of several days' continuance, accompanied with a diarrhœa and tenesmus, &c."

Swelling of the breasts occurs sometimes in the earlier months of pregnancy, so as to produce much pain and fever; besides the inconvenience to the mother, it causes considerable determination of blood from the uterus, depriving the fœtus of much nourishment, and thus tending to produce abortion; among other bad effects which tight lacing produces, is that it injures the proper development of the nipples during pregnancy. In such cases, you will find benefit by putting thick ivory rings over each nipple, so as to defend it from the pressure of the dress, and thus allow it to attain its proper size. Where there are no symptoms of plethora present, you must be careful to avoid lowering still further the strength of the patient, and here a mildly invigorating tonic plan of treatment must be had recourse to. "For a number of years," says Mr. White, of Manchester, "I have been convinced of the good effects of cold bathing not only in preventing miscarriages when every other method has been likely to fail, but other disorders which are incident to pregnant women, and generally attendant upon a weak, lax fibre. I dont mean the cold-bath in the greatest extreme, but such as that of Buxton or Matlock, or sea-bathing; or bathing in a tub in the patient's house with the water a little warmed. I have frequently

advised my patients to bathe every other day, at a time when the stomach is not overloaded, and not to stay at all in the water, to begin this process as early as possible, even before they have conceived, as there will be then no danger from the surprise, and continue it during the whole term of pregnancy; and several have bathed till within a few days of their delivery."

"We are warranted by long experience to declare that unless plethora produce some direct evidence of its mischievous tendencies, as headach, pain in the chest, or sense of fullness in the head upon stooping, giddiness, &c, the patient should not have recourse to bleeding without the express approbation of the physician. To women who are in the habit of miscarrying this proscription of indiscriminate bleeding is particularly important, especially as it is the remedy almost universally resorted to for its relief, than which, in many instances, nothing can be more preposterous or improper. We are justified in saying it has very often produced the evil it was intended to prevent*."

In cases of this sort, where there is much constitutional atony, our attention must be first directed to the state of the alimentary canal; the chylopoietic functions must be duly regulated, and, for this purpose the mildest laxatives, and gentle alterative medicines, must be exhibited; this being done, we may now gradually feel our way with tonics, as quinine and sulphuric acid, and, perhaps, even proceed to the use of chalybeates; the food should be nourishing but unirritating, and perfectly easy of digestion; she should live in a pure air, use moderate exercise, and keep early and regular hours.

Where, however, premature expulsion of the fœtus has become so habitual as to resist the various modes of treatment which I have recommended, the only remedy, which I know of, is strictly to avoid all sexual intercourse for twelve or fourteen months, or even longer. During this period, the uterus, from not being exposed to any excitement, become less irritable, and gradually loses the disposition it had acquired of expelling its contents prematurely, and I have known this plan to succeed in cases where the strictest attention to diet and regimen, and the most careful avoiding any cause which might excite uterine contraction, had failed. Although abortion or miscarriage may have repeatedly taken place, still we ought not to give up all hope of the patient being able to carry the fœtus to the full term of uterogestation. Dr. Young, of Edinburgh, in his lectures on midwifery, mentions a case where the patient actually miscarried thirteen times, and yet bore a child the fourteenth time. This, however, is very rare, and I do not quote it to show that premature expulsion may occur several times with impunity, far from it. "The consequences of repeated abortion," says

Dr. Dewees "are 1st, a bad state of leucorrhœa; 2nd, immoderate flow of the catamenia, attended very often by the expulsion of coagula, their returning too frequently, or that distressing condition of this discharge called dysmenorrhœa, or painful menstruation; 3rdly, dyspepsia, with all its terrible penalties; 4thly, schirri and cancers, besides many other evils of minor importance. The catalogue here exhibited is not the sportings of the imagination, it has but too real a foundation as every practitioner of experience can safely testify."

So much, gentlemen, for premature expulsion of the fœtus. You are aware that this is the subject for the best essay on which I have proposed to give the midwifery prize next spring, and having reason to know that several among you have determined to compete for it, I have purposely quoted, during the present lecture, most of the best authorities upon the subject, in order that you may be better acquainted with its literature. At our next meeting I shall commence the description of labour.

LECTURES

ON

FORENSIC MEDICINE,

DELIVERED BY

DR. HAY GRAHAM,

At the Westminster School of Medicine.

LECTURE XV.

Insanity, continued.

GENTLEMEN,—In my last lecture I enumerated the various species and symptoms of monomania, of mania, dementia, and congenital idiotism. It now remains to point out to you more particularly those diagnostic characters by which you may distinguish the disease when feigned, and detect it when concealed.

Ancient history, both sacred and profane, presents us with several illustrious examples of this disease being feigned. In our own day it is of frequent occurrence, in order to avoid the punishment due to premeditated guilt. If it thus becomes a matter of importance to detect the imposition when feigned, it is no less important to detect its presence when concealed. Hence your testimony may be frequently required both in civil and criminal cases; either to ascertain the presence of insanity on a commission *de lunatico inquirendo*, or on a disputed will, or on a criminal prosecution; and, as the court would feel itself bound to decide according to your testimony, it is highly incumbent on you to make yourselves acquainted with all the forms of insanity, so that you may be enabled to form a correct judgment, and deliver your evidence in a manner at once clear, concise, and convincing.

In ordinary cases, the points to which you should more particularly direct your attention are, first, the state of the mind, secondly, the

* Dewees on Children.

external appearances, and, thirdly, the history of the disease. There are two pathognomonic symptoms of the mind which are never feigned; during the period of remission, the really insane believes himself to be perfectly sound, and rather seeks to conceal his insanity than to render it more apparent: the impostor, on the other hand, asserts his madness and overacts his part. The most unerring symptom, which nature does not allow to be simulated, is that watchfulness or want of sleep which almost invariably accompanies insanity, and without producing any listless exhaustion or other usual effects. The countenance assumes an expression corresponding with that peculiar state of the mind which constitutes the insanity, and does not lose this expression when not observed; the actions, attitudes, and gestures, have also a corresponding relation to the mind. In nearly every case of insanity the previous history and invasion of the disease are sufficiently well marked and known as to leave no doubt respecting the part which is acted; but, if otherwise, the medical man ought to examine the individual and obtain from him a history of the disease, which, in all probability, would bring to light some circumstance that would at once detect the imposture. Mr. Hill makes mention of the peculiar odour observed in maniacs, with which the sheets and body linen are impregnated of such as sleep in a small badly-ventilated room, and which, to those acquainted with this peculiar smell, can scarcely ever be mistaken. Dr. Rush relates a case of suspected insanity in a man under sentence of death, and which had been declared to be feigned, but was subsequently ascertained really to exist by the increased frequency of the pulse, being twenty strokes in a minute more than it ought to have been in a healthy state of mind and body. In some forms of the disease there is great torpidity in the alimentary canal, and should a brisk purgative or powerful emetic fail to produce any effect, although their action would not prove the negative, yet the want of action, joined with other corroborating circumstances, might be considered as positive proof of the presence of the disease. Foderé, after enumerating the characteristic symptoms of mania, dementia, and monomania, observes, that a pretended madman answers insanely on every subject besides that on which he pretends to have lost his senses; he carefully avoids, on all occasions, to show the most feeble glimmering of reasoning, least his imposture should be discovered. If any speech is made in his presence, without his being sensible of the design, in which either a severe punishment is announced or a great benefit held out, he is not so completely master of himself as not to allow his emotion or feelings to become known or visible either by his words, his actions, or his countenance. Such unexpected communication of the destiny which awaits him, is, says Foderé, a touchstone that seldom fails.

Thus, a woman, who associated with a band

of highway robbers, frequently escaped from justice by pretending madness. Foderé, being ordered to visit her, was himself deceived, and on the point of declaring her insane; but remembering a case related by Zacchias of a physician who ordered an impostor to be soundly whipped, upon a principle, that, if the disease were real, it would be serviceable in producing a determination of the morbid humours towards the surface, and, if feigned, that it would detect the imposture, he turned back towards the door of the cell, and addressing the jailer in a firm tone of voice, said, "To-morrow I shall return; if she continues to scream and howl, and does not dress herself; if the chamber is not cleaned and put in order, you will have ready a red-hot iron to apply between her shoulders." These words produced the desired effect; the next day she was dressed, her room washed and arranged, and she had passed a quiet night. Foderé then examined her, and in the course of a fortnight fully detected the imposture, and made his report accordingly.

"The best mode," observes the editor of Dr. Bech, "that has yet been discovered for forcing a man who feigns madness to confess and desist, is by the use of the whirling chair, that is, a chair placed upon a spindle, which revolves upon its own axis, and is turned by a wheel or crank, with the rapidity of the fly of a jack: it produces nausea, even to syncope; and after two minutes of such discipline, few men can command spirits sufficient to act any part." It was by this means that Mc. Dougal, of Glasgow, was rendered sane when he feigned madness to avoid being tried for sinking ships, to defraud the underwriters. But he betrayed himself to the medical men by the common fault of impostors, not having "a method in his madness," but mixing up the two irreconcilable characters of

"The moping idiot, and the madman gay."

In the majority of cases there is no difficulty in distinguishing real insanity, yet there are some where it is difficult to form an opinion. First, for some individuals, who are considered sane, in many respects approach very nearly those who are insane; and secondly, on the other hand, many who are deranged preserve sufficient good sense to appear possessed of their understanding.

Under the first head may be considered, first, those whose understanding is weak and limited, having but little knowledge and an imperfect education, and who, on this account, may entertain an erroneous judgment, strange fancies, and ridiculous opinions; secondly, those half-witted people who have just sufficient judgment and discernment to enable them to conduct the ordinary affairs of life, but not duly to appreciate the motives which give rise to their actions and regulate their conduct; thirdly, those who have a superficial knowledge, are ever busy without well knowing what they are about, and are always

distracted without being able to fix their attention; who have a lively imagination, never at rest, but in a continual flutter of mobility; strange and singular ideas; a peculiar method of seeing every thing; and a mania for some particular thing—for dogs, or horses, or building; for collecting prints, purchasing rare paintings, or buying up old books, of which they make no use; hence the satirist—

“These learned men of books assume the care,
As eunuchs are the guardians of the fair;”

and other such like hobby-horses, whims and caprices. Fourthly, those who are enslaved by their passions, carried away by the impulse of feeling, violent, impetuous, and imperious; unable to endure contradiction or to resist their unbridled desires, neither possessing the light of reason nor the discipline of early education to controul or correct their passions; the ungovernable rage of these seems to be an innate feeling—to proceed from a sort of blind instinct rather than from any want of understanding. Fifthly, those lunatics who have been cured, but still retain some trace or taint of their disease, and continue susceptible, irritable, inattentive, and unsteady. Sixthly, such as are easily frightened, or alarmed, without reason, and always in a state of doubt, perplexity, and confusion. Seventhly, the longings of pregnant women, or the capricious desires of such as are nervous; that change of character which is produced by menstruation, or by a morbid state of the brain in hysteria or hypochondriasis, or by any other cause.

Under the second head may be included, first, those individuals on whom insanity makes such a slow and gradual progress, that, as it steals on them imperceptibly, they have been long labouring under the influence of the disease without having excited any suspicion. Thirdly, some cases of monomania, where the delusion is very limited, and the individual is capable of discerning the absurdity of his delusion, and can, therefore, conceal it. Thirdly, a slight degree of mania, where the mind is simply on the stretch with some enthusiasm; these are merely exalted, and talk a great deal without degenerating into absolute insanity. Fourthly, under this head may be ranged the first stage of primitive dementia, and the commencement of dotage, or the weakening of the intellect in old age. Fifthly, that species of monomania, not unfrequent with women, which consists almost entirely in a perversion of their sentiments towards their children, their husbands, their friends, or relations. Sixthly, where the insanity is dissembled, as may be observed in those who watch an opportunity to commit suicide, or those who have sufficient tact and judgment to recognise the object of an inquisition, or of those appointed to examine them. Seventhly, that insanity which is of short duration, such as is induced by drunkenness, or by epilepsy. Eighthly, the lucid intervals between the paroxysms of intermittent alienation.

In all these cases, touching the bounds of demarcation, it is difficult to ascertain the absence, or to deny the presence, of insanity. In respect of the passions, it is an old observation, that they give rise to temporary madness. “*Ira brevis furor;*” hence some authors have proposed as questions—1st. Whether a violent passion may not be considered as a fit or paroxysm of monomania? 2nd. Whether a predominant or exclusive passion may not excite for the time being, that is during its existence, a state of temporary derangement? In whatever way these questions may be decided, they cannot, in a moral point of view, remove the responsibility of the agent; for, being previously in a sane state, he ought to have exercised sufficient control not to have allowed his passions to be so highly excited; and such an apology for crime would not, in a court of justice, be of more avail than a plea of drunkenness, which is never admitted.

The celebrated Dr. Gall, the founder of the science of phrenology, in his work on the Functions of the Brain, relates many singular cases of insanity, especially of monomania, by way of establishing his doctrine; viz. that each convolution is a particular organ, and that each hemisphere is a perfect brain; as each eye is a perfect organ of vision, which can act either conjointly or independently of the other. Thus, should one of the hemispheres of the brain become incapable of performing its functions, the other may continue to act without any apparent diminution of intellectual capacity; or, should the functions of the one become partially deranged or suspended, those of the other may remain perfect and undisturbed.

Tiedemann mentions the case of one Joseph Moser, who was insane on one side of the brain, and perfectly sane on the other, and was hence capable of observing his own insanity. At Vienna, a minister of state laboured during three years under a similar disease. He heard some one continually talking and uttering abuse on his left side, so that he always turned his eyes to that side, notwithstanding he distinctly perceived with his right side that these sounds proceeded from a derangement on the left side of his head. When he was attacked with a fever, he was no longer able to resist this illusory impression; and long after he was cured, each time he committed an excess in drinking, or allowed himself to be highly excited by passion, he was sensible of a tendency to a relapse on this side of his head.

Dr. Gall relates several other cases in confirmation of the above. In addition to these he gives the case of a priest, who for some time was afflicted with erysipelas on the forehead, which frequently disappeared, and again broke out: he gradually became paralytic on the left side, and was at last seized with apoplexy, and died in the course of a few hours. Three days previously, he had preached a

sermon and followed his usual occupation as a schoolmaster, without his intellect being in the least affected. On opening the body, the right hemisphere of the brain was found disorganised, converted into a substance of a dirty yellowish white colour, and full of hard knotty points or tubercles, resembling grains of sand.

Cases of monomania, or partial derangement, where only one or more organs of the brain are diseased, are of extremely frequent occurrence, and to be met with in every lunatic asylum. Having, in my previous lecture, entered very fully into the symptoms of this form of insanity, it is not necessary to trouble you with many illustrations. The inimitable Cervantes has delighted the world with a most admirable, though fictitious, description of this species of madness, in his celebrated hero Don Quixote. Here the disease is painted in vivid colours, and under the simplest form, being confined to one object. The Don was an accomplished scholar, and a courteous gentleman; he could converse on every subject like one of the sages of Greece, except on deeds of arms and chivalry. The moment this subject was introduced, his whole thoughts took one particular bent. "Alas," exclaimed the knight of the sorrowful figure, "the days of chivalry are gone. The world has become degenerate; virtue is abashed, and vice stalks abroad with unblushing front; where now is Amadis de Gaul, and the Paladins of Charlo-man? Knight-errants no longer scour the earth to punish the vicious, reward the virtuous, and relieve the distressed damsels. It is for me to revive the long-forgotten profession of arms; to restore the lustre of the days of the Paladins; to punish wicked necromancers and hoary headed magicians, and to relieve distressed enchanted virgins." Thus thought, spoke, and acted the Don.

Many believe themselves inspired of heaven. The asylum at Hanwell at this moment contains a very ingenious, and, in other respects, sensible young woman, who, without having previously learnt the trade, has taught herself and other lunatics to plait straw, and manufacture bonnets, and, in all respects, is discreet and well conducted. Being unfortunately a follower of the Rev. Mr. Irving, she believes she has the gift of the unknown tongue, that the Holy Spirit resides within her, and uses her tongue as an instrument to utter its warnings to a sinful world. This idea has steadfastly taken possession of her mind; well acquainted with the sacred writings, she defends her insanity with much skill. In her the forehead is well formed; the organs of ideality and perception are largely developed.

In these cases of monomania, or partial derangement, we meet with such a mixture of reason and extravagance, of correct judgment and delusion, that it is often extremely difficult to ascertain the existence of the disease; and, as the patient is himself firmly persuaded of his sanity, a casual observer, and even those

appointed to visit and examine them officially, are frequently imposed upon by these deceptive appearances. Every work on mental alienation abounds with these cases. Pinel relates several; thus one monomaniac succeeded in persuading an officer of government appointed to visit the lunatic asylum, or "l'Hôpital de Bicêtre," that he was the victim of the grasping avarice and cruelty of his family, so that the officer, having examined his grounds of complaint, intended to set him at liberty. But, at the moment of departure, when saying farewell, that he should shortly return and communicate good news; "your excellency," replied the other, "will be always welcome, provided you do not come on a Saturday, for on that day the blessed Virgin pays me a visit." A commissioner whose duty it was to set at liberty those who were considered cured, having examined an old vine-dresser, and observing no incoherence in his answers, prepared a document, or "procès verbal," attesting his cure, which, as usual, was handed to him for signature. What was the surprise of the magistrate on seeing that he assumed the title of Christ, the Saviour of mankind, and gave himself up to all the reveries which this idea suggested. Thus a similar case of monomania is related by Lord Erskine, in his celebrated speech for James Hadfield. "I examined," said his Lordship, "for the greater part of a day, an unfortunate gentleman, who had indicted a most affectionate brother, together with the keeper of a mad-house at Hoxton, for having imprisoned him as a lunatic, whilst, according to his own evidence, he was in his perfect senses. I was, unfortunately, not instructed in what his lunacy consisted, although my instructions left me no doubt of the fact, but, not having the clue, he completely foiled me in every attempt to expose his infirmity. You may believe that I left no means unemployed which long experience dictated, but without the smallest effect. The day was wasted, and the prosecutor, by the most affecting history of his unmerited suffering, appeared to the judge and jury, and to a humane English audience, as the victim of the most wanton oppression; at last Dr. Sims came into court, who had been prevented by business from an earlier attendance. From him I soon learned that the very man, whom I had been above an hour examining, and with every possible effort which counsel are so much in the habit of exerting, believed himself to be the *Lord and Saviour of mankind*, not merely at the time of his confinement, which was alone necessary for my defence, but during the whole time he had been triumphing over every attempt to surprise him in the concealment of his disease. I then affected to lament the indecency of my ignorant examination, when he expressed his forgiveness, and said, with the utmost gravity and emphasis, in the face of the whole court, '*I am the Christ!*' and so the cause ended."

The monomania of religion frequently leads

to the most horrible crimes, under the persuasion of performing an acceptable service to the Deity, and, by saving their souls from perdition, conferring an inestimable benefit on their victims. Pinel mentions the case of a superstitious countryman, whose imagination being highly excited by the sermon of a missionary, believed himself doomed to the horrid and eternal punishment which awaits the damned, to be plunged into another Phlegethon, there, amidst sulphureous flames, to be tormented by fiends of horrid shapes, to linger for ever and ever, and, though immortal, to endure all the excruciating agony which "mortal flesh is heir to," though never to die yet to feel for ever dying. These horrid thoughts haunted his imagination, and he believed that, in imitation of our Saviour's sacrifice for the sins of the world, he could only rescue himself and his family from such a dreadful destiny by, what he termed, making them martyrs by the *baptism of blood*. In pursuance of this idea he first attempted to murder his wife, who with great difficulty escaped from him; he then infuriated raised his murderous arm against his two youngest children, and, with the barbarity of fanatic zeal, immolated them in order to procure eternal life. Delivered into the hands of justice, he murdered one of the prisoners confined in the same cell, considering it a meritorious work of expiation. His madness being proved he was condemned to be confined for life in the Lunatic Asylum of Bicêtre. The isolation of long solitary confinement, which invariably exalts the imagination, and the idea of having escaped from death, notwithstanding the sentence of the judges, aggravated his disease and increased the delusion, so that he believed himself to be invested with the attribute of the Deity, and was omnipotent, or, to use his own expression, that he was the fourth person of the Trinity; that he had received a special mission to save mankind by the baptism of blood, and that all the potentates of the earth combined could not take away his indestructible life. His derangement was partial, and limited to what was connected with religion, and he seemed, in every other respect, to enjoy the most perfect reason and use of his senses. This patient having passed above ten years in close confinement, and having preserved an appearance of calm tranquillity, was allowed to enjoy the liberty of the precincts of the hospital. Four additional years of probation had elapsed, sufficient to induce a belief in his cure, when suddenly these superstitious and sanguinary ideas again took possession of his mind. On the eve of Christmas he conceived the project of making an expiatory offering of all who should come in his way. Having furnished himself with a shoemaker's knife, he seized the moment when the guardian went his rounds, and stabbed him behind, the blow was fortunately turned aside by the ribs; he then cut the throats of two lunatics near him, and would

have continued his destructive course of homicide, had he not been speedily seized hold of, and the further consequence of his ungovernable and murderous rage thus put a stop to.

Dr. Gall relates the case of Koerper, the chief of those fanatics who attempted to found a new sect in religion. This man, whose countenance was calm, yet confident, and beaming with candour, declared that, from his earliest remembrance, religion took exclusive possession of his thoughts, he therefore sedulously applied himself to the study of the sacred writings, and of the commentators thereon; but the great variety of opinions amongst them convinced him this was not the right mode of discovering the true religion; he, therefore, renounced his studies and all further research, but betook himself to prayer, and fervently entreated the Deity, if not contrary to his immutable decrees, to reveal the truth. Having prayed for a long time, he one night saw his chamber filled with a brilliant light, as bright as that of several suns. In the midst of this dazzling burst of glory our Lord Jesus Christ appeared to him, and revealed the true religion. Koerper endeavoured to propagate his doctrines with an indefatigable zeal, which he considered obligatory upon him, and it was impossible to make him sensible that his mind had wandered in the midst of illusions. Perhaps if we were acquainted with the private history of the Rev. Mr. Irving, and the unknown tongue, some allusion similar to this might appear.

Pregnancy is rarely an exciting cause of insanity. M. Esquiroi quotes the case of a lady, who twice became mad on the first day of conception, but each time the disease lasted only a fortnight. Labour is frequently a predisposing cause of insanity; yet the disease seldom declares itself without some moral cause exerting its influence on the mind. Strange unnatural dreams, or longings, frequently accompany pregnancy. Gall relates the case of a lady, who, on seeing the naked arm of a baker, felt an irresistible desire to bite a piece out of it, a gratification her husband procured for her on paying an adequate sum of money to the baker to tear a little bit out of it. There is another account of a woman, who had a horrible longing to eat her husband; to gratify this unnatural desire she killed him, boiled and roasted a part, and salted the rest, and lived upon him for several months.

We sometimes meet with cases of intermittent insanity, where the disease is periodic. M. Pinel mentions one, in which the paroxysm lasted eight or ten days every month, producing a most complete change of character. During the lucid intervals this individual was calm, gentle, and reserved; his answers were diffident and full of propriety; he was distinguished by the urbanity of his manners, his strict sense of justice, and his willingness to oblige, and offered ardent prayers for his reco-

very; when the paroxysm returned his face became flushed, his eyes red, sparkling, and prominent; he felt a burning heat in his head, accompanied with great thirst; his step became quick and impatient; the tone of his voice hoarse and arrogant; and his look full of daring, and he experienced a violent desire to quarrel and fight with every one. Another lunatic, naturally mild and peaceable, during the period of exacerbation, seemed inspired by the demon of malice. The mischievous activity of his mind was never at rest; he would lock up his companions, beat, provoke, and excite them by every means to quarrel.

It is, in point of fact, extremely necessary not to confound, or mistake, any other species of insanity with that which is intermittent, and which alone can properly be said to have lucid intervals. For any act, committed during such intervals, is binding in law; for your better guidance I therefore give you the definition of a lucid interval, as eloquently described by Dr. Aguessan. "It must not be (says the Dr.) a superficial tranquillity, a shadow of repose, but, on the contrary, a profound tranquillity, a real repose; it must be not a mere ray of reason, which only makes its absence more apparent when it is gone; not a flash of lightning, which pierces through the darkness only to render it more gloomy and dismal; not a glimmering which unites the night to the day, but a perfect light, a lively and continued lustre, a full and entire day, interposed between the two separate nights, of the fury which precedes and which follows it. To use another image, it is not a deceitful and faithless stillness which follows, or forebodes a storm, but a sure and steadfast tranquillity for a time, a real calm, a perfect serenity; in fine, it must not be a mere diminution, a remission, of the complaint, but a kind of temporary cure, an intermission so clearly marked, as in every respect to resemble the restoration of health."

A lucid interval, says Harlam, is a complete recovery of the patient's intellects, ascertained by repeated examinations of his conversation, and by constant observation of his conduct for a time, sufficient to enable the superintendent to form a correct judgment.

Lord Thurlow defines it a perfect interval, not a cooler moment, an abatement of pain or violence, or of a higher state of torture, a mind relieved from excessive pressure, but an interval in which the mind, having thrown off the disease, had recovered its general habit.

Such is the definition of a lucid interval in civil cases, but, in criminal cases, it is of greater latitude. Sir Vicary Gibbs, at the trial of Bellingham for the murder of Mr. Percival, asserts, that a man may be deranged in his mind, his intellects may be insufficient to enable him to conduct the common affairs of life, disposing of his property, and have trustees appointed him, yet such a man is not discharged from his responsibility for criminal acts, *if he possess a mind capable of distin-*

guishing right from wrong. On the same trial, Lord Mansfield declared, that so long as lunatics could distinguish good from evil, so long would they be answerable for their conduct.—*Bech*, p. 246.

Thus, gentlemen, you perceive by these definitions, there are two kinds of lunatics in point of law; one, who, from aberration of mind, is not capable of managing his affairs, and another, who is not capable of distinguishing right from wrong. The one is not bound by the civil law, but still remains amenable to the criminal law, the other is not amenable to any law. Upon this principle Earl Ferrers, though certainly a lunatic, was condemned and executed for the murder of his steward, and upon the same principle was Bellingham condemned for the murder of Mr. Percival.

Having, since I last addressed you, visited the lunatic asylum at Hanwell, it is with a feeling of satisfaction I have it in my power to offer my testimony to the judicious and scientific method on which this institution is conducted. Dr. Ellis, the first medical officer or director of the establishment, has the merit of being the first who combined the moral with the physical treatment for diseases of the mind. It is clear, whatever may be the cause of any disease, in order to effect a cure it is first necessary to remove that cause, for it is an old maxim, "*causâ ablatâ, effectus tollitur.*" When the cause is of a moral nature, which by mental irritation has produced a physical disease, moral remedies must be administered, combined with such as are physical. Hence gentleness and persuasions combined with firmness, the "*suaviter in modo et fortiter in re,*" is the proper mode of administering relief "to a mind diseased" from blighted hopes, disappointed affections, the loss of friends and fortune, and all those numerous ills which beset the path of life. An entire stranger to Dr. Ellis, I know not what may be his pretensions to originality, or how far he may be indebted to others for his ideas, but this, gentlemen, I know, that humanity is greatly indebted to him for having introduced into this country a mild, scientific, and more efficacious method of treating these diseases of the mind, the most sad and humiliating to which our nature is subject. It is Dr. Ellis who has banished from the houses of refuge for the insane the whips, the scourges, and the chains, which once in effigy disgracefully ornamented the gates of Bethlehem. This philosopher, a physician in the truest sense of the word, following the indications of nature, has, by the most simple means, succeeded in the cure of a great number of lunatics too numerous to mention, whose cases, considered incurable, had for years baffled the skill of every medical treatment. The benevolent countenance and plain unaffected good sense of this gentleman reminded me of the Man of Ross, none of the pedantic affectation of learning, the arrogant assumption of superior merit, or the quackery

of science. His method is to allay the irritation of the mind by a mild and soothing treatment; no harshness is exercised even towards the most refractory; they are mildly but effectually prevented from either injuring themselves or others; no solitary confinement for any, where the mind, left without resources, preys upon itself, and feeds the disease; all that are capable of so being are engaged in active employments, which require no application of thought, and therefore relax the mind; the more robust are employed in the open air, the labours of the field, and such like occupations; those of a more delicate frame or feeble constitution remain in the house, where, in well ventilated and long corridors, heated by steam, they breathe a pure air, and enjoy a climate superior to that of Italy, a perpetual spring, such as poets describe; 'twas a luxury to walk along them, an artificial climate, such as not a nobleman of the land enjoys. Those in whom the disease is of a milder form, are, according to their sexes, classed together, whilst the more violent maniac and demented idiot, the dulness of the one acting as a sedative to the excitement of the other, and vice versa, thus producing a mutually beneficial effect, inhabit the same division of the building. Considering the nature of the inmates, a place "where folly holds her court," the greatest order and decorum prevail. All who have any glimmer of reason, are sensible that restraint is imposed upon them for their benefit, and not for their punishment, that they are treated as recoverable beings, and not as brutes or criminals. All seemed content and happy, as far as happiness and content are consistent with such a condition. Those who remain in the house, either from delicate health, a peculiar state of mind, or previous habits, and are capable of employment, are variously occupied. Workshops are fitted up for tailors and shoemakers; a long corridor forms a rope walk for the women, where they are actively employed in making twine, others plait straw, and manufacture bonnets, others are engaged in the domestic affairs of the establishment,—all are more or less occupied. Every operation of the more usual trades and all the business of the place are carried on by the inmates, under the discreet guidance of guardians. The master mind of Dr. Ellis is the moving principle, which conducts, directs, and puts all in motion. In a word, this receptacle of madness contains within its walls a well organised community.

The manifold advantages of such a system are obvious; constant employment diverts the attention, and leaves the mind in repose; the mild and equable temperature renders additional clothing unnecessary, even in the severity of winter; it also produces a determination towards the surface, and removes congestion, it promotes cutaneous excretion, and restores the equilibrium of circulation, and what is more, as the whole animal

system is a chain of sympathies, it promotes the healthy functions of every organ; and as the whole end and aim of medicine is to assist and correct nature, that is, to restore these functions, it greatly diminishes the need of pharmaceutical remedies. This is an immense advantage, giving the *vis medicatrix* of nature an opportunity of throwing off the disease, either by some salutary crisis of her own, or by a more slow and gradual operation, undisturbed by the blundering administration of ill-judged remedies, or the experimental attempts of vain theorists, more frequently aggravating the malady than effecting a cure.

Having given you this brief and imperfect account of the asylum at Hanwell, I shall now conclude this lecture and the subject of insanity with the plain, simple, and therefore philosophical, remarks of Dr. Ellis. "Every case of insanity," observed the Dr., "whatever may be its cause, whether moral or physical, is attended with inflammation of the white (or misnamed medullary) substance of the brain. On dissection, the vessels are, to a greater or less extent, invariably congested, according to the violence and extent of the inflammation. As the disease continues its march, greater or less disorganisation ensues; sometimes a part or the whole of the brain is reduced to a soft pulpaceous mass, at others it is firm and compact; the pia mater frequently adheres so strongly to the convolutions as to be separated with great difficulty; this increased vascularity extending to the periosteum additional osseous matter is secreted, the substance of the skull is thickened, the cellular structure of the diploe disappears, the sutures are no longer to be seen, and the whole assumes a degree of solidity resembling ivory. When the disease is of long standing, and the whole brain is involved in the organic lesion, and is no longer able to perform its functions, fatuity is the necessary consequence, and the excitement ceases, there being no longer any organ to excite. This, gentlemen, is the usual termination of chronic insanity, and thus the raving maniac, should death not put an earlier period to his existence, sinks into the tomb a dull unconscious idiot.

In delivering these remarks on the public asylum at Hanwell, without having received the sanction of Dr. Ellis, with whom I have no acquaintance beyond that of a stranger visiting the institution, I beg to observe, that if there are any misstatements, either in my account of the place or of the doctor's theory of mania, I alone am responsible for the errors or omissions which may be found. My hasty visit not having exceeded half an hour, I have not been able to give so full and perspicuous a description as I should have wished to have done, and as I hope at some future period to have it in my power to do.

Reviews.

An Exposition of the Nature, Treatment, and Prevention of Continued Fever. By DR. M'CORMAC. Pp. 202. Longman. 1835.

THE author commences his work with a truism, that "the importance of fever is very great," and he might have followed it up with another, that its nature is unknown.

From the father of physic up to the present period, during the space of above two thousand years, the subject of fever has afforded a theme for the disquisitions of many of the most eminent physicians during this long stream of time, and yet we know little more than did Hippocrates, and it may be thousands of years hence ere the essence of this disordered condition shall be revealed. Every thing yet respecting it is but conjecture; hypothesis has supplanted hypothesis. Doctrines the most improbable, nay, the most absurd, have been propounded and received by their contemporaries; wild speculations which have floated for a while, and which are recorded by tradition, have been successively subverted, affording but, it must be confessed, cold consolation to philosophers.

But we are now in an era of science, a bright era, it is said, yet, perhaps, no more luminous than when Galen lived, or when Nero reigned on the imperial throne.

All the efforts of ingenuity, and all the stores of philosophy unfold to us no more than that fever consists of an assemblage of phenomena,—symptoms sometimes following each other in regular succession, sometimes bursting forth spontaneously, and at others occurring in irregular order. We agree with Dr. Southwood Smith's hypothesis in the order in which the different systems of the body generally become affected in fever, but, in subscribing ourselves his proselytes, we are, nevertheless, of opinion that he extends his views further than facts or physiology will warrant. Our author *denies* Dr. Smith's positions, but does not *disprove* them. We are not bigoted to any philosophical sect or doctrine; we would receive the doctrine of Sir Richard Phillipps, and at once discard the Newtonian theory, if the former could be more satisfactorily demonstrated.

Dr. Smith thinks he proves his points satisfactorily, but the details require confirmation; we shall come to this anon. After some general observations on the fallacy of taking the effect for the cause, or the cause for the effect, of characterising a disease from the symptoms displayed in but one of its stages, we come to the following quotation from Dr. Smith, referring, however, more especially to the errors committed in neglecting the *common* symptoms of fever, and the *order* in which they manifest themselves. With respect to the order of appearance of the symptoms, he says that "our guide is *invariableness* of con-

currence. If we can ascertain that a certain number of events *invariably* takes place in every form and every degree of fever, these events will give us the particular phenomena which are common to all the varieties of the disease. If we can further ascertain that these events *invariably* concur in a certain order we shall have discovered what events bear to each other the relation of cause and effect."

Dr. M'Cormac is not a convert to these sentiments, we do not wish him; collision often elicits truth. He concludes, without adducing facts or solid arguments, that "it is, however, exceedingly difficult to affirm anything with certainty on this head, for sometimes these three classes of functions appear to be affected consentaneously, and not unfrequently they follow a different order from that here laid down; hence the difficulty of predicting any given series of symptoms." This is assertion, not proof. Here the author is speaking of typhus fever. It would be useless to present the symptoms which are narrated as characteristic of that disease, it will suffice to aver, that by the author's observations nothing new on this head has been elucidated.

With regard to the pathology of fever, three questions may be legitimately presented. 1st. Is fever the result of local inflammation in one or more organs of the body? 2dly. Is fever inflammation of the entire sanguineous system? 3rdly. Is it an affection *sui generis*? These are texts for an octavo!

Let us refer to these different propositions, *seriatim et singulatim*. Broussais, the distinguished French pathologist, referred fever to gastro-enteritis; he believed that here was the origin, here the invariable origin, and fever the consequence. Clutterbuck raises its seat to a more lofty elevation, he believes it to arise in the head. It may appear strange that organs so distant, and so dissimilar in their structure and vital properties, should have assigned to them identical morbid phenomena; but it is true they have. Each of these pathologists, with a host of others, denies the occurrence of *idiopathic fever*. We dissent *in toto* from their opinion. We are of opinion that the fire of fever may be lighted up in the system at large, be diffused over the whole frame, and concentrate its fury upon any local organ; at one time in the head, at another in the lungs, and at another on the mucous lining of the alimentary canal, so that fever shall accrue and exist for an indefinite period without any form or grade of inflammation having a being. With some of those sentiments Dr. M'Cormac is in accordance.

"Is fever inflammation of the entire sanguineous system?" The question could not assuredly be answered without previously entering into a long preamble of what is inflammation,—a question more easily proposed than answered. Fever certainly bears an analogy to inflammation; it is designated an excitement. Excitement of what?—Of the nervous and vascular systems; debility of the

muscular, (and perversion of the secretory, system.

"Is it an affection *sui generis*?" No one has answered the question. But let us leave the regions of physiology, and descend to perhaps really more useful domains, to a few opinions of the author. They shall be cursory. We think it may be established as a general rule, that fever, when once it is fully developed, cannot be arrested, it will pursue its path, but nevertheless its path may be shortened. Diet, air, medicine (of course), with an infinite and innumerable variety of other auxiliaries, can, fortunately for the practitioner, abate the violence of the disease and shorten its duration.

The author is a contagionist. He asks, "Why are not all fevers contagious?" And he shrewdly observes, "I can make no reply, except that all fevers may perhaps become so under certain conditions." The author is not, however, thoroughly satisfied about this point; he feels his incapability to untie the knot, more especially as Dr. Armstrong varied his opinion; he did not know the Doctor, or he would have known that no worse authority could have been quoted, and that the Doctor often changed his opinions.

On the pathology and on the morbid appearances after death the Doctor dwells at large; he endeavours, with great judgment, to lay down rules which may enable us to discriminate during life any individual organ which may be the seat of local disturbance in fever, such as inflammation, ulceration, &c. After referring to the brain and lungs, we are brought to the abdomen. The observations on the affections accruing in the latter cavity were exceedingly interesting. "The next," he says, at p. 103, "and very important complication of fever which I shall notice, is the abdominal. It is to be regretted that almost all the distinctive diagnostic tokens here are very uncertain. So long as the fever persists, abdominal complications are commonly associated with it; but it is very difficult to ascertain their kind. Neither the appearances of the tongue nor the sense of local pain, are any sure indices. It has been satisfactorily determined by Louis, Andral, and others, that the various conditions presented by the mucous membrane of the mouth and tongue depend as much upon the idiosyncrasies of the individual, as upon any connexion with any peculiar condition of the stomach or other portions of the intestinal canal. Hence the association of a red pointed tongue with the gastro-enteritis, supposed by Broussais to constitute an integral part of fever, is anything but correct. How often do we witness every variety in the aspect of the tongue, without being able to connect it with any serious affection of the digestive tube. Nor is it easy on the other hand to analyse the morbid signs presented by the whole frame, and refer them to the lesions which have produced them. The connexion of the appearances of the

tongue with the general issue of the disease, is much more certain and satisfactory. But, after all, what does it teach us? When the fever sets in, the tongue becomes red or white, then foul, hard, discoloured, chapped and dry; and, when convalescence begins, the tongue grows soft, moist and clean. The changes are concurrent, and we hardly see any alterations in the state of this organ, which precede the after phenomena of fever, so far as to foretell their issue. From the occasional softening, to the injection, inflammation, ulceration, and perforation, which may occur in the mucous membrane of the stomach, or any other portion of the intestinal tube, with the exception of the last-mentioned, we possess no certain sign, apart from the general state and progress of the patient. The existence of that affection of the mucous follicles called dothino-enteritis, is indicated by no individual sign, though many French pathologists maintain that typhus itself is the result, and, consequently, the presumed token of this lesion. The extensive ulcerations which occur in various portions of the mucous lining of the intestinal tube, are frequently unaccompanied with any uneasiness, even from pressure. Considerable pain upon pressure of the epigastrium or abdomen is, however, in general, justly considered a sign of the progress of internal mischief and organic change. But that such a token is very often illusory, will appear from the circumstances just mentioned; and the additional facts noticed by Andral and others, of the occasional excessive natural sensibility of the abdominal parietes, and also of the pain arising from pressure, owing to other causes, such as those cases in which blood is effused into the interstices of the abdominal muscular tissue. It has been determined by Alison, within the sphere of his own observation, that the pustular affection of the mucous follicles, and the ulceration, upon which so much stress is laid by French pathologists, are less frequent in Edinburgh, at least, than in Paris. In twenty cases which he examined, he only detected ulceration once. He looks upon it as more frequent in children. The researches of Bright and several others, nevertheless, show that these lesions occur sufficiently often, both in Britain and Ireland, to keep up the wakeful attention of the practitioner. Pain is generally an attendant on peritonitis from perforation and effusion, unless in extreme prostration, as well as in peritonitis from other causes; the latter occurrence, however, as well as the former, is rare in fever. The encouragement and swelling of the mesenteric glands, sometimes accompanied by purulent deposition, are indicated by no known sign; it is truly remarkable how these glands come to be so quickly affected in fever. A dysenteric or diarrhoeal discharge is said to point out an affection of the large intestines, and constipation one of the small; but, as every observer must remark, there is nothing constant in such indications. Diarrhoea, as

also vomiting, seldom occur except in early stages of fever; they are no certain accompaniments of organic abdominal changes. A diarrhoea sometimes precedes a sudden alteration for the worse, and sometimes it is the prelude to convalescence. It is more frequent than vomiting, but, from the common use of purgatives, it is not always easy to know the artificial from the natural evacuation. Certainly, when the discharge proves obstinate, and of longer continuance than usual, I would suspect an abdominal complication. We know that a kind of typhoid dysentery, or dysenteric typhus, is sometimes prevalent. As a general rule it may be here observed, once for all, that in the course of fever of low excitement, frequently called typhus, or when prostration sets in during the course of fever, the pain attending all inflammatory or other organic complications, is little or none."

With respect to the prognosis in fever, one of the most difficult and delusive points, the author assents to the almost universally recognised proposition, that *danger of the patient is in a ratio to the extent and violence of the structural and functional lesions.*

Early prostration is unfavourable. Inflammation occurring soon after the invasion of the disease, is less to be dreaded than when the health has become deteriorated by the continuance of the disease. "The occurrence," he says, "of thoracic inflammation is worse than abdominal, and cerebral than thoracic; the three united are, *à fortiori*, worst of all." The veriest casuist would concede to this latter conclusion.

The author divides the treatment of fever into three classes; first, those cases which are controllable by medicine, and which recover; secondly, those which terminate fatally; and, thirdly, those which run their course and terminate favourably without the aid of medicine, &c. The remedial agents to be employed in these various forms, and in an infinite variety of grades, must be modified by circumstances. If local inflammation arise, it must be combated by blood-letting, purgatives, blisters, &c. If in the brain, the scalp must be shaved; if there be heat in the head, cold applications must be applied. The latter point is one which we fear practitioners frequently fall into error in—it is, continuing the cold application even after the temperature of the scalp has been reduced to its natural standard, or even below it. It is a mischievous error. When the heat of the head is not above par, and the cerebral disturbance continues, a blister to the scalp may be judiciously applied. The cold must certainly be discontinued.

No matter where inflammation sets in, nor at what period or stage of the disease, it must be attacked, and, if possible, subdued. In the treatment, we perceive nothing original, save, perhaps, that *a lemon cut in two and applied to the burning temples affords relief.*

We have entered somewhat fully into Dr. McCormac's work on Fever. The author writes

from close personal observation of the disease in "three different quarters of the globe," and from experience in his own person. The book contains little philosophical or scientific inquiry. It gives an elaborate account of the various opinions entertained on the subject in ancient and modern times, and on the Continent, as well as in Ireland, respecting this dire and Protean malady. The remarks on the treatment are copious, but not less interesting. We have no doubt but that, as the author has produced a very favourable impression on our minds from the careful perusal of his work, many will be anxious to read it. It contains all we know or believe on fever; we strongly recommend it to our professional brethren.

On the Preparation and Medicinal Employment of Aconitine, by the Endermic Method, in the Treatment of Tic Douloureux and other Painful Affections. By A. TURNBULL, M.D. Pp. 48. Longman, 1834.

The author, in a work recently published *On the Endermic Use of Veratria and Delphinia*, hinted that aconitine might be discovered, and, if so, appropriated to medicinal purposes. After a laborious inquiry, the substance was detected. It being the opinion of Dr. T. that all other preparations of aconite were objectionable on account of their varying so much in strength, which they are found to do, and in consequence of the unpleasant, nay painful, effects of this agent, when internally administered, the Doctor prefers its external application, when such effects are not found to ensue. An account of the processes for preparing the active principle of the aconitum napellus may be interesting to our readers.

"A quantity of the fresh root of the aconitum napellus must be procured, and care should be taken that it be sound, and that the root be that of monkshood, for sometimes other roots are sold for it. Let it be carefully and cautiously dried, and then reduced to powder. This latter operation is not unattended by danger, especially if a part of the fine dust, which rises from it, be inhaled. One part by weight of the powder, and two parts by measure of strong alcohol are to be digested together in a gentle heat for seven days, and the tincture, while warm, is to be filtered. It is then to be reduced to the consistence of an extract by careful evaporation, at a low and well regulated temperature; the object of this is to prevent the destruction, or expulsion, of the active principle, which would very probably ensue, if the temperature employed were higher than barely sufficient to carry off the alcohol. To the extract thus prepared liquor ammonia is to be added, drop by drop, and mixed well with it, to precipitate the alkaloid; and, in this part of the process, care must be taken that too much be not added, as, in some instances, the product appears to have been decomposed by inattention to this circumstance.

It is difficult to give a precise rule as to the quantity, but enough will have been added, if the extract give out the odour of ammonia when stirred.

“The mass now consists of impure aconitine, mixed up with a quantity of extractive and other matters, soluble in water, and it may be taken up either with boiling alcohol or sulphuric acid, or the soluble matter may be removed by repeated washings with small quantities of cold water, which will leave the aconitine. This latter process is the one we have generally employed, and is performed by pouring a little water on the extract, and, mixing them carefully together, then allowing the undissolved part to subside, pouring off the fluid, and repeating the operation as long as any soluble matter is taken up; a quantity of light brown, or grey, powder is left, which may be purified by subsequent solution in alcohol. This powder contains the active properties of the aconite, in a high degree of concentration. A grain of it was dissolved in a drachm of alcohol, and twenty drops of the solution, put into the mouth of a Guinea-pig, occasioned death in a few minutes. Other experiments have been performed, all of which show the extreme energy of the substance.

“The second process consists in dissolving the alcoholic extract, prepared as before, without the addition of the ammonia, in as much cold water as will take it up, and carefully decanting the solution from the insoluble part, and then filtering it. To the filtered solution liquid ammonia is to be added, drop by drop, as long as it occasions any precipitation. When the precipitate has subsided, the supernatant fluid should be carefully poured away, or drawn off by means of a syphon; and, after the precipitate has been deprived of as much of the fluid as possible, it should be purified by a sufficient number of washings with small quantities of cold water, and then carefully dried. The product obtained by this process is white.”

In tic douloureux, and other nervous affections, and in gout and rheumatism this remedy has been employed.

An ointment is to be made, consisting of “*R. Aconitinæ gr. ij., alcohol. gtt. vj., tere optime et adde axung. ʒj., ut fiat unguent.*” The quantity of the aconitine is to be increased daily, but cautiously, to four, and even eight grains; the author has prescribed eight grains in a severe case of tic. A small portion of this ointment is to be rubbed over the painful part three or four times a day. The friction is to be continued until either the pain abates, or its common effects appear, viz. a sensation of heat, prickling, and feeling of constriction in the part. These sensations will sometimes last for hours. Dr. Turnbull has found this remedy serviceable in a number of cases. We notice one of tic in the portia dura and fifth pair of nerves, another of neuralgia of the left side, another of tic in the infra-orbitary nerve. Two

other cases are presented which occurred in the practice of Mr. Lyon, of Montague-street, and at the end of the treatise is a reprint of the cases reported in our Journal, Dec. 13th, 1834, taken from Dr. Roots's practice in St. Thomas's Hospital.

We have no doubt but that there lie hidden in the mechanism of the universe remedies for every disease, if we did but know where to find them.

Dr. Turnbull deserves well of his professional brethren for directing their attention to the medical agency of the ranunculus class of plants. Their chief action on a healthy person appears on the nervous system, a fair inference that it will be so in disease.

THE

London Medical and Surgical Journal.

Saturday, February 14, 1835.

THE COLLEGE OF PHYSICIANS.

It gives us great pleasure to be able to state from good authority, that the Government have held several conferences with the heads of the College of Physicians, the purport of which was the settlement of that portion of the question of reform in their antiquated institution which interferes with the giving of superior advantages to those gentlemen who have obtained collegiate degrees.

That the result of these consultations will be highly favourable to the medical world and to society in general, we think cannot be doubted, as any obstinate leaning on the side of the Fellows to the abuses which have so long disfigured their College cannot but be vain. The latest hour of their misrule is come, and their portals must be opened widely to admit the visitation they can no longer resist.

One of the proposals of the Government is, we believe, that the fellowship, the highest honour in the gift of the College, and too often the talisman of introduction to lucrative employment, shall not for the future be confined solely to those who have attained collegiate degrees, but that a plan, more just, appropriate, and liberal,

of admitting a certain mixed number of Licentiates yearly to that dignity, shall be adopted; thus successfully levelling one grand point of exclusiveness hitherto maintained, and infusing that snug coëterie, so sparing of their favours, with a more vigorous and liberal vitality.

With regard to the licentiate-ship, as the first step to future honour and emolument, it ought to be open to all possessing the requisite medical knowledge; and of course, to this end, the heads of the College would be allowed to frame such a scale of study to be gone through preliminarily as should be sufficient to enable the candidate to pass a searching but impartial examination, the *locus in quo* of study being disregarded. And this ordeal again should, if possible, combine both practice and theory, not merely the latter, as is the case at present. For this purpose a certain number of cases should be placed under the management of the candidate, and his capability of treating them noted by officers properly qualified and appointed for that purpose. The mere theoretic examination now undergone, every medical man knows to be no test of competence; and, since the College of Physicians will still remain possessed of extensive privileges, they ought to bestir themselves to become deserving of so much distinction, and add this desideratum in their form of examination, so much practised abroad, so easy of adoption, but so shamefully neglected here. In taking so much trouble upon themselves, they would join to the empty honours, which now create little else but jealousy toward their body, a degree of usefulness which should merit the respect and thanks of society; in other words, their stagnant waters would become a fertilising stream.

In this mode, then, by increasing the

number of admissions, and bestowing them annually on those most distinguished for professional eminence, looking at the solid attainments of the applicant for a licentiate-ship instead of cavilling about the spot where he might have obtained his information, a most beneficial amelioration in the highest branch of our profession would be achieved. No violence, no rasing of an ancient institution would be required, but only a gentle bending of its obliquity back into its natural straightness; in a word, an applying of the College to the purposes for which it was originally designed. And to suppose that the parties implicated in this change will be wrong-headed enough to reject so reasonable a quantum of reformation, would be to believe them so desperate as to defy public opinion, the verdict of their humbler brethren, and to invite those strokes from the scythe of destruction, which, by a timely taking of the pruning-hook into their own hands, might be easily avoided. So great a degree of madness entering into sane minds is not to be anticipated; we shall consider the question, therefore, so far settled.

Such an amount of reform, then, having been once conceded, on its coming into operation would gradually lead to the most desirable results. The accession of talent accruing to the *effete* and musty ranks of the reigning clique would sweep away for ever the list of absurd bye-laws, which renders them the scoff or hatred of the profession in general, would conciliate public and professional good will, and, finally, render the College of Physicians that palladium of public security against empiricism and the reckless daring of ignorance, for which it was first intended.

THE COLLEGE OF SURGEONS.

At the same time that the above salutary alterations take place in the College of Physicians, a similar but greater amount of improvement, without doubt, will be exhibited in that of the Surgeons. The close divan of the latter will assume less of a Turkish character, and its high and exclusive bye-laws, calculated for the meridian of Constantinople, undergo a change suited to the times and to public opinion.

THE ADULTERATION OF DRUGS.

THE jurisdiction of the Apothecaries' Company, if reform in the Colleges of Physicians and Surgeons be properly effected, is drawing to a close. Their rule, which never should have been extended to its present limit, will be curtailed. That society, originally formed for the sale of unadulterated spices and drugs, must revert to its ancient occupation, and leaving the examinations of medical candidates on the one hand, and their own personal aggrandisement on the other, confine their future labours to the less ostentatious employment of detecting fraud, in so far as concerned with their especial province, and vending wholesome, and, if possible, cheap drugs.

That their body, certainly a trading one, should ever have overleaped its plainly defined limits, and transgressed on those of science, will be matter of wonder to a more improved age, and, perhaps, may not be the fault so much of its own arrogance and avidity after gain, as of the inert and inefficient laws with which a science *they* were pleased to recognise as a kindred one was begirt. They made the best of the opening which avarice exhibited to their view, and pride spurred them on to enter those boundaries out of

which they are now about to be summarily, if not disgracefully, ejected. They and their Latin pedagogue (for, lacking the power of judging of a classical education by their own attainments, they employ such a personage) are about to disappear from the stage of their half trading, half scientific, lucubrations for ever. A more congenial duty will devolve on their worships than now engages their bewildered senses,—that of tasting and smelling sophisticated drugs, in order to condemn them, and thereby doing that service to the state which their sorry examinations in the sciences of anatomy and surgery cannot confer. The hue and cry is loud and long among medical practitioners, that their medicines are shamefully adulterated, and each asks the other, with a rueful face, if there be no remedy for so crying an evil. We presume to foretel that the government will assign this smelling and tasting task to its proper professors, the Masters, &c., of the Worshipful Company of Apothecaries. Their other and smuggled province they must resign. Peace and resignation be with them*!

* The sophistication of drugs in the shops of inferior apothecaries and druggists exceeds belief, and unless put an end to by a rigid scrutiny on the part of those who have the power, either the College of Physicians or Apothecaries' Hall, bids fair to neutralise the effect of any prescription offered. Rhubarb is almost uniformly more or less adulterated with turmeric, and jalap with one half linseed meal! Each petty apothecary has his own made compound called ext. coloc. comp. Their syrup of poppies is composed of treacle and opium, and their, ought to be, distilled waters made with lump sugar, common water, and a few drops of the essential oil required! Look to this, ye vigilant guardians, too well paid for nought.

Foreign Medicine.

Action of the Lymphatics.

In the course of a few months, M. Pannizza, of Pavia, will publish a work on the Lymphatics, which, it is expected, will attract great attention. In it he confirms the opinions of Mascagni with reference to the lymphatic vessels; and he further proves, contrary to the researches of M. Lauth, of Strasbourg, and of M. Lippi, that if a part of the substances absorbed by the lymphatics enters into the veins, its passage takes place only through the medium of the ganglion, where it is taken up by the radicles of the vein itself, which arises from the ganglion. M. Pannizza possesses, perhaps, the finest collection ever seen of preparations illustrating the lymphatics of the genital organs: they were made by himself.

Bulletin Médicale de Bourdeaux.

Fatal Mistakes in Dispensing.

Several cases have been of late recorded in the various foreign and British Medical Journals of fatal consequences resulting either from error in dispensing or in prescribing: occasionally the wrong drug being written in the physician's prescription, as recently at Paris, the sulphate of morphia in lieu of the sulphate of quina; and sometimes the wrong drug being dispensed by the chemist, as recently at Brussels and Paris, the bi-chloride of mercury in the place of the proto-chloride. To prevent, in some measure, the occurrence of this accident, a writer in one of the French Medical Journals, which has lately come under our notice, recommends that whatever *new names* may be (perhaps of necessity) adopted in chemistry, to designate the same article, they should be restricted to that science only, the old name being retained for prescriptions, &c., as many of these errors arise from the multiplicity of names indicating a single drug; calomel, for instance, having about as many as a Spanish hidalgo. If this plan were adopted, he contends corrosive sublimate could never be given in mistake for calomel.

This proposition would certainly be of advantage—there cannot be any doubt on that score; but even its adoption would remove little more than a third of the evil, whilst the plan enforced in the Russian Pharmacopœia, as recorded in the *Bulletin Médicale Belge*, is far more extensive, and, consequently, more useful, inasmuch as it would tend to prevent the injurious consequences resulting from an error in the prescription, as well as in the dispensing, and there would then be only one source of mischief remaining.

The plan we have already mentioned of employing only the old names of drugs will be so far of use, that it is suited to the capacity of the majority of those who compose the class of druggists, and their apprentices, of the pre-

sent day;—of course we are alluding to Great Britain only; on the Continent they are well educated men, who have passed the necessary examinations. Here, any individual who pleases, even if his pharmaceutical knowledge be not more extensive than an acquaintance with rhubarb and salts, may become a chemist and druggist, and with him, consequently, such a mistake as giving a poisonous dose of the pulv. ipecac. comp. instead of an emetic of the pulv. ipecac. might readily happen, and indeed has happened. The plan alluded to of the Russians does not include any measures for the prevention of any errors which may arise from the ignorance of the dispensers, such not being presumed to be in existence, as all their chemists are duly and severely examined. The remedy is in the hands of Parliament, and to that legislative body we leave it.

We shall now proceed to detail, in a few words, the regulations of the Prussian Pharmacopœia. The authors of that work have drawn up a table of heroic medicines, with the largest doses which ought to be given appended, and no physician may prescribe, or any druggist dispense, larger quantities, unless a note of admiration (!) be attached. If this were done in all cases, the druggists would be aware when the physician really meant to increase the dose, and also when a mistake had been made; at any rate, should the one prescribe or the other dispense without this mark, the responsibility and the punishment would attach to one person only, and to him deservedly, as such an error would be decidedly owing to the most culpable negligence.

The Statistics of Forgery, Suicides, Rape, and Murders, in France, England, and Spain.

BY M. JULIA DE FONTANELLE.

M. Chevallier published in the *Journal de Chimie Médicale*, for July, 1834, an interesting essay on falsified writings, in which he gave the statistics of this crime in France from 1825 to 1831, inclusive. His calculation gives, as the medium, about 283 every year, whilst in Great Britain there have been only 417 in eleven years, that is, about 43·4 in each year.

We have felt some curiosity to ascertain the relative number of forgers in the two most highly civilised nations, and in the one in which, while ruled by the Arabs, arts, letters, and sciences, were successfully cultivated, and which now, under the iron rod of its institutions, cannot keep pace with the progress of ages. Many documents upon Spain have been consulted, among others, the *Foreign Quarterly Review*, vol. 5, *One Year in Spain*, *Hawkin's Medical Statistics*, &c., and we are satisfied that in the year 1826 there were forty-five forgeries committed. Now, if we compare these numbers with the population of the three kingdoms, calculated as follows,—

France (in 1831) . . . 32,560,934 inhabitants,
 Great Britain (1831) 20,721,350,
 Spain (1826) . . . 13,950,000,
 we shall have, for every million of inhabitants,—

in France 888 forgers,
 in England 220,
 in Spain 320,

which gives,
 for France 1 in every 113,635,
 for England 1 474,500,
 for Spain 1 312,567.

Thus we perceive, that, of the three kingdoms, France reckons the greatest number of forgers. The causes of this cannot be attributed to the progress of the science of chemistry in this kingdom, because Spain, which is the least advanced of these three nations in that respect, counts a larger number of these criminals than England, which latter is the rival of France.

But, by way of compensation, in 1826 * Spain could count only

Suicides † 16
 Infanticides ‡ 13
 Poisonings 5

We may perceive that in these respects it yields to England and France. The same may be said of duels §; they are so rare in Spain, that in 1826 there only occurred four.

In regard to rape,
 in France (1831) there were 69, or 1 in every 470,000,
 in Spain (1826) there were 62, or 1 in every 240,000,
 in England (1831) there were 77, or 1 in every 180,000.

This fact gives rise to a curious remark; it is, that neither the climate nor the violence of the passions renders the crime of violation more frequent, as it might have been supposed, since France offers the fewest, and in England they are more than double the number of those in France, and a third more than in Spain.

Finally, homicide and the temptations to crime are in Spain forty-five times more

frequent than in France, and twenty-seven times more so than in England; and it may be affirmed that, with the exception of Dalmatia, there is no other country in Europe, not even Corsica, where there are so many assassinations attempted or completed as in Spain.—*Journal de Chimie Médicale et de Toxicologie.*

Amputation of the Leg for Caries of the Bones of the Tarsus—Torsion of the Arteries, notwithstanding considerable softening of their Tunics.

BY M. AMUSSAT.

M. Delm, an advocate, thirty years of age, suffered for the first time, when seven years old, from pain in the left ankle. This pain recurred occasionally, but always yielded to rest.

Three years ago the pain became much greater than he ever before experienced; the ankle swelled for the first time, and the patient was obliged to use crutches. Repose, emollients, and discutient applications were employed, but unavailingly, the disease continued to make progress.

Amputation was now recommended as the only means of preserving life, but the patient rejecting this proposal, he was recommended to try the baths, and accordingly went successively to Aix la Chapelle, Bagnères, and Aix in Savoy. The douches which were employed caused the formation of several fistulæ, from which unhealthy pus was evacuated, and sometimes small portions of bone. His strength and courage were now much diminished, but during his six weeks' residence at Aix in Savoy, his appetite and strength returned; he became stouter, and the pus which passed from the fistula became lactescent and inodorous.

He returned to Paris, cheered with the hope of avoiding the operation; but some time afterwards he again lost ground, the pain became as severe as ever, and the discharge unhealthy. Diarrhœa supervened, and had continued for a month, when M. Amussat saw him; it soon ceased by the administration of kino.

M. Amussat saw him for the first time on the 18th of January, 1833. The patient presented at that time a most deplorable appearance; the lower half of the body, including the abdomen, was completely anasarcaous; the penis was three times its natural size, and almost diaphanous, the scrotum being equal in size to the head.

A consultation was held on the case, and amputation was determined on, and performed on the 20th. The muscles were soft, discoloured, infiltrated, and, as it were, macerated; the coats of the arteries were softened, and were surrounded by a lardaceous substance, which seemed to form a canal round those vessels and the nerves; both the external and the internal membranes of the

* The year 1826 has been chosen because the most exact details relative to that period could be obtained.

† Suicide is less frequent in Spain than in any other country; this is owing not merely to religion, but because it is considered a crime.

‡ Infanticide is very rare in Spain. If it were compared with any other state, Russia, for example, we should see that with an almost equal population there are nearly 100 infanticides in the year.

§ The same remark will apply to duelling as to suicide. It is a crime punished by the death of the survivor, and when therefore one takes place, it is generally without seconds. This circumstance may tend to render statistical details imperfect.—TRANS.

arteries were easily lacerable, but yet torsion was successfully performed, and without pain. On examination of the part which had been removed, the os calcis and the lower part of the fibula were found to be engaged in the disease, the former very extensively.—*Gazette des Hôpitaux.*

On the effects of General Bleeding in two cases of Dropsy, one Acute and Idiopathic, the other Symptomatic.

COMMUNICATED BY M. TARDIEU, M.D., AT SANGUES.

J. H. du Cros, residing at Sangues, was engaged, in the year 1833, in mowing a meadow. While in a state of profuse perspiration, he rashly plunged both the fore-arms into a fountain of very cold water. The next day he was labouring under violent fever; a physician, one of the supporters of the doctrine of *la médecine expectante*, was called in; he ordered little else than a nitre drink. When I saw the patient eleven days after, I found him in the following condition:—the countenance flushed and swollen; dyspnoea considerable; pulse intermittent, hard, and frequent; suppression of urine. He laboured under ascites and anasarca; the scrotum and penis were infiltrated.

He was forthwith bled freely from the arm, and the next day, relief having been experienced, the bleeding was repeated; no medicines were given. In the course of four days the anasarca had disappeared; a few spoonfuls of oxymel were given as an auxiliary, and in the course of another eight days the patient was well.

B— had been suffering for three years from dyspnoea and insomnia. His medical attendant, considering his complaint to be simply asthma, contented himself with the administration of some diuretics. Another physician, who was consulted occasionally, thought he had discovered an aneurism of the heart, and even located it in the right auricle. He accordingly ordered bleedings, digitalis, squills, &c. But the ordinary medical attendant of the family, who was a partisan of the *médecine expectante*, forbade the bleedings, and threatened his patient with dropsy if he submitted to them. The patient became alarmed, and refused to be bled, but notwithstanding ascites ensued.

When I was called in, the patient presented the following symptoms:—Complete insomnia for the last month, with orthopnoea for the same period; countenance flushed and swelled; eyes projecting; pulse intermitting, tumultuous, and disappearing occasionally under pressure; the pulse at the wrist is isochronous with that of the heart; ascites and anasarca, the latter also affecting the genital organs; suppression of urine for the last three days. The patient, who was only in his forty-sixth year, and of a strong constitution, was in such a state of suffering, that he had attempted suicide.

He was immediately bled to eighteen ounces from the arm. In order to ascertain what effect it would produce, I ordered all medicines to be omitted. In the course of twenty-four hours he was improved. The day after the next he was bled again, and twenty leeches applied to the region of the heart; the dyspnoea ceased, and the anasarca gradually disappeared. He was then ordered digitalis internally and externally, according to M. Chrétien's method; squills were also employed; and, in twenty-five days, he was cured, the pulse and the heart had almost resumed their normal condition, and the patient employed himself in his ordinary occupations, which he may doubtless be able to do for a long while, if he pay particular attention to the rules of hygiene.—*Journal de Médecine et de Chirurgie Pratiques.*

Analysis of the Bark of the Prunus Virginiana.

BY STEPHEN PROCTOR.

This bark contains fecula, resin, tannin, gallic acid, a fatty matter, lignine, red colouring matter, volatile oil, hydrocyanic acid, salts of lime and potass, and oxide of iron.

The volatile oil of the bark of the prunus Virginiana is very analogous with the essential oil of bitter almonds; it produces the same effect on the system, and may be employed as its substitute. Two drops killed a strong cat in five minutes. Dr. Conwel, in his Dissertation on Vegetable Chemistry, says he procured an alkali from the bark of the prunus Virginiana, which he called cerasine, but Mr. Proctor is of opinion that it is only a salt of lime.—*Journal of the Philadelphia College of Pharmacy.*

Analysis of the Cimicifuga Racemosa.

BY MR. JOHN FITZMAN.

The root of this plant, the only part of it used in medicine, is composed of a fatty matter, gum, fecula, resin, tannin, wax, gallic acid, sugar, oil, a black colouring matter, a green colouring matter, lignine, salts of potass, lime, magnesia, and iron.—*Op. cit.*

Foreign Hospital Reports.

HÔTEL DIEU.

Cerebral Congestion, consequent on Violent Grief, treated by Bleeding.

A woman, about 54 years of age, was admitted into the Salle St. Lazare, of the Hôtel Dieu, and placed under the care of M. Chomel. She is the widow of an old soldier; about four years ago several circumstances happened which caused great mental anxiety. Towards the middle of January this was renewed, in consequence of which she was seized with severe headach, soon followed by delirium. She was brought to the hospital two days afterwards, and passed the first night furiously delirious. When visited the next day, the face was flushed, the forehead hot, the eyes glaring, conjunctiva injected. The delirium had somewhat abated, and she could answer a few questions correctly. She was accordingly asked if, previous to her attack, she had not suffered from violent grief. She replied in the affirmative, and appeared to be then much disturbed. She was immediately bled from the arm, and had mustard pediluvia. The next day, all the bad symptoms ceased, and three days afterwards, she left the hospital.

Slight Pneumonia, with Pleuritic Effusion.

A young man, about twenty years of age, was admitted into the clinical ward, under M. Chomel, on the 18th of January, with the following symptoms:—Decubitus dorsalis; wandering pain over the whole of the right side of the chest; slight difficulties of breathing; cough, with expectoration tinged with blood; dull sound and obscurity of the respiratory murmur, with resonance of the voice in the two lower thirds of the right thoracic cavity; the pulse was scarcely increased in frequency, and there was not any disorder of the digestive tube or of the nervous system. These symptoms commenced about five or six days previous.

In this case, M. Chomel considered the diagnosis to be rather difficult. The viscid expectoration, partly bloody, left no doubt as to the existence of pneumonia; but were the dulness of sound and absence of the respiratory murmur to be considered equally indicative of the inflammatory action in the lungs? M. Chomel decided in the negative. Percussion affords a dull sound, and the voice becomes resonant, only when the lung is hepatised. Now the absence of fever would not allow of the surmise of hepatisation of two of the lobes of the right lung. M. Chomel was therefore of opinion that the dulness of sound, and the absence of the respiratory murmur were owing to the presence of a certain quantity of fluid effused in the pleura, and that there was present a slight pneumonia, and in the first degree only. Venesection was performed.

The progress of the case proved the correctness of the diagnosis. The crepitating râle, which was not audible at first, was heard in proportion as the effusion diminished. The absorption of the fluid took place rapidly, and, some days after, the respiratory murmur could be distinguished, and also a sound as of friction caused by the false membranes which were becoming organised on the surface of the pleura.

HÔPITAL SAINT LOUIS.

Fissure at the Anus—Excision.

CASE I.—A young woman, æt. 25, was admitted into the Salle Saint Augustin of this hospital, on 10th Dec., 1834, under the care of M. Jobert. She is of a nervous and very irritable temperament, and has never enjoyed good health. The menses commenced between fifteen and sixteen, but are always very irregular. She became pregnant in the beginning of the year 1833, and went her full time. The process of parturition was protracted, but not unnatural.

On recovering from the puerperal condition she became subject to the following symptoms: great constipation and severe colic, the passage of a stool requiring great efforts, and the feces slightly tinged with blood. She was also subject to pains in the side, a feeling of weight in the pelvis when walking, and itching of the anus and vulva. To relieve this condition she had recourse to baths, and used to introduce into the vagina a sponge soaked in a decoction of Provence roses and wine. She again became pregnant, but aborted about the second month, as she believes, five months after her first labour.

Four days after abortion had taken place she was admitted into the Hôtel Dieu, where prolapsus uteri was discovered. Leeches to the groin and general bleeding were prescribed, and then a pessary was passed, but without relief. She soon left the Hôtel Dieu, and five weeks after gave up the pessary on account of the pain it caused. She did not have recourse to any other plan of treatment, until her admission into the Hôpital Saint Louis.

With the assistance of a speculum, a spot of ulceration was discovered on the os uteri, which was cauterised three times. The woman declared that she had never had syphilis. She compared her feelings when at stools to a sensation of tearing and almost insupportable burning pain, which induced M. Jobert (who has often seen ulceration of the cervix uteri accompanied with fissure at the anus) to examine that part, when he discovered a small superficial ulcer situated at the posterior part between the folds of this opening.

On the 27th Jan. the woman was placed on the edge of her bed as for the operation for fistula, when M. Jobert took hold of the part containing the ulcer with a pair of forceps, and excised it. No dressing was applied, but the patient had a sedative and a semicupium.

The relief experienced was very great and almost immediate; the feeling of weight and pain in the pelvis ceased almost entirely, and what little remained was attributable to the disposition of the uterus to become prolapsed. The stools passed easily, and nearly free from pain, except a slight burning sensation from the passage of the fæces over the lips of the wound. The bowels were kept open by occasional doses of Seidlitz water, also by the administration of enemata. The incision cicatrised by the 19th, and the ulcer of the uterus healed by the 25th. She was discharged on the 26th of January.

CASE II.—A female, 28 years old, of feeble constitution, always labouring under ill health, and peculiarly liable to colds, was admitted the 11th of November, 1834. She has never suffered, she says, from any venereal disease.

When about 13 years old, she fell upon the edge of a stool, by which the labia majora were much contused, and an abscess formed. She has since then laboured under leucorrhœa. Six weeks after this fall, menstruation commenced, but has always been performed irregularly, and at each menstrual period she had violent attacks of colic. This continued up to the period of her marriage, about twenty months ago; leucorrhœa remained, and to it were now superadded severe pain in the matrix, and a feeling of weight in the pelvis. She became pregnant, which added materially to her sufferings, for by the time she had reached her fifth month, she could not walk, on account of the violence of the pain in the uterus. This organ, she stated, always seemed to her as if on the point of being prolapsed, when she stood upright. The labour was natural, but the leucorrhœa afterwards increased, and the pain, which at first appeared to be lessened, became more intense.

She had been always constipated, but much more so during pregnancy, and she then discovered that she had piles which bled when at stool. About a year before she married, she perceived a burning sensation, and severe pain when passing an evacuation; during pregnancy, and after parturition, these symptoms increased very much. Latterly, indeed, she has also had a most intense feeling of tearing and burning pain in the part.

Up to the time of her admission into the hospital, nothing had been done to relieve her. An examination was forthwith made with the speculum, and the neck of the uterus was ascertained to be ulcerated. Caustic was applied, and severe bronchitis followed; three weeks afterwards the application was repeated, and the bronchitis reappeared, so that the caustic was abandoned. The escharotic employed was the acid nitrate of mercury, and after each application the gums swelled, and slight salivation ensued. This woman had never been mercurialised.

From the symptoms under which she laboured, M. Jobert suspected the existence of

anal fissure, and an examination proved that he was correct. A similar operation to that of the preceding case was performed, and with a like success. Relief was almost immediate, and no bad symptoms retarded the cure. By the 26th of January, the wound had healed, but she was then under treatment for the ulceration of the cervix uteri.

DEATH OF M. DUPUYTREN.

THE eloquent professor of the Hôtel Dieu, the illustrious successor of Petit and Dessault, the rival of the most celebrated surgeons in Europe, the master of so many promising pupils, the hope and honour of the French schools of surgery,—in a word, the celebrated Dupuytren is dead. He expired early in the morning of Sunday last, after an illness marked by extreme suffering, the fatal results of which he fully anticipated, and the symptoms of which he actually analysed during their progress.

Guillaume Dupuytren was born at Pierre Buffiere, in the department of La Haute Vienne, on the 5th of October, 1778. His parents possessed but very slender means, and never intended to have sent him to Paris; but, while still a child, an officer of a regiment of cavalry quartered in the town was struck by his physiognomy, and offered to take him with him to the capital. The proposal was accepted, and at twelve years of age, in the year 1790, he commenced his career, and was shortly introduced to M. Thouret, a celebrated physician, who thoroughly appreciated his abilities, and conceived a great affection for him. Dupuytren was admitted as a Surgeon of the 2nd class on the 26th Fructidor of the year 10, Doctor in 1803, Assistant Surgeon-in-Chief, in 1808, and in 1812 he obtained, in a contest with a host of talented competitors, the Chair of the Professor of Surgery. In 1815 he was appointed Surgeon-in-Chief of the Hotel Dieu, and Member of the Institute in 1818.

His works are numerous on Anatomy, Physiology, and Pathology, besides various other treatises. M. Dupuytren was first attacked in November, 1833, by a slight fit of apoplexy, the result of which caused a slight paralysis of the mouth, and a difficulty in expressing himself, which induced his numerous friends to urge him to abandon his labours, and seek a renewal of health in Italy. He accordingly quitted France for Rome and Naples on the 24th November, 1833. In March, 1834, he returned to Paris, and apparently recovered, when he immediately renewed his lectures at the Hôtel Dieu, and presided at the surgical examination in the Ecole de Médecine. He probably here contracted a second disorder, which added to the effects of the first, and unfortunately the nature of this disease, which was pleurisy, was at first mistaken, attention being entirely devoted to-

wards a cerebral affection. In July last he resolved to try sea-bathing, but at the end of a month he returned to Paris worse than he set out. The disease had now made so decided a progress, that it was no longer possible to be deceived in its character. Every means were employed, but to obtain relief only, as the cure was not in the least probable, and he finally expired at half-past three on the morning of the 8th instant, in the 56th year of his age, in the full possession of his faculties to the last. To the last moment he gave professional advice; and, on the evening preceding his death, he caused his journal to be read to him as was his custom.

M. Dupuytren has left a large fortune. The principal dispositions of his will are known. He leaves to the Faculty of Medicine two hundred thousand francs for the endowment of a Professorship of Pathological Anatomy, which will be open to competition. It is the intention of the Faculty to erect at the same time, in their new hospital, a Museum of Anatomy, to be called the *Musée Dupuytren*. MM. Sanson and Bégin are charged with the termination of his "Memoir on the Shape;" M. Marx will edit his other publications, and succeeds to all the instruments of his late master and friend. M. Dupuytren has left his library to his nephew, and he has not forgotten his assistants in the Hôtel Dieu, or his domestic servants.

According to his latest desire, he has bequeathed his body to MM. Broussais and Cruveilhier, who, in conjunction with Professor Bouillaud, MM. Delmas and Marx, have performed the autopsy. The brain presented a remarkable volume: its weight, after having been perfectly dried was 2lbs. 14ozs.; in the right lobe traces were found of the former apoplectic rupture. The right pleuritic cavity contained a quantity of serous matter; the heart was very large, and weighed 20ozs., its ordinary weight being about 12; the kidneys were softened, and contained gravel.

DR. INGLEBY'S ILLUSTRATIONS IN MIDWIFERY.

Irregularity in the form of the Abdomen.

We occasionally meet with a singular deviation from that uniformity in the shape of the uterine tumour which characterises pregnancy: I allude to a partial and circumscribed elevation of the uterine tumour continuous with the general development, and neither affected by the position of the body, nor materially changed by pressure. It is not unlike a fibrous tumour developed under the uterine peritoneum, in advance of the surrounding parts, and has not, I think, been distinctly described by authors. This deception appears to have influenced the medical officers of a public Institution in the case of a woman far advanced in pregnancy, and in whom the

uterus chiefly occupied one side, and resembled two large steatomatous tumours. Although I am not prepared to say that the appearance may not sometimes consist in an irregular development of the uterus, I incline to the opinion that it is occasioned by a faulty state of the abdominal parietes, resembling in this respect a partial vesico-vaginal hernia. It is, perhaps, occasioned by a separation of the recti muscles. In persons, at least, who have borne many children, the irregularity in the contraction of the muscles not unfrequently occasions a very pointed deformity of the abdominal coverings. In one such instance, after the birth of an unusually large child, I could easily have passed my hand through the aperture.

Auscultation.

Upon the subject of auscultation I have scarcely anything to advance. Although far from an expert auscultator, I have very distinctly detected both the soufflet and the pulsation of the foetal heart by means of the stethoscope as well as the naked ear. But the soufflet is common to several diseases, and is therefore an uncertain evidence of pregnancy. This sound will be rendered obscure when the centre of the placenta corresponds with the centre of the fundus uteri on its posterior surface, and (as Dr. Rigby observes) will be scarcely perceptible when the placenta is attached to the uterine orifice. The pulsation of the foetal heart is of course conclusive of the presence of a living child within the abdomen. This sound is not distinctly heard before the fifth or sixth month, at least I have not been able to distinguish it at earlier periods; a circumstance referable, perhaps, to my own experience in auscultation. The pulsation of the foetal heart may also be too feeble to be communicated to the ear. In the case of Cæsarean operation before mentioned, the foetal heart could not be heard to pulsate, notwithstanding a most minute examination by several practitioners. The patient persisted, however, that she felt the child move, and it was extracted alive. The waters had been evacuated a long time, and the pressure which the uterus made upon the body of the child, I conclude, rendered the pulsations of the heart too feeble to be distinguished.—*The Dublin Journal of Medical and Chemical Sciences.*

In the development of the nervous system of man, he passes through the various forms which this system presents, from the very first nervous data in the polypus to its full perfection in man. Man displays the perfection of organisation; he stands pre-eminent in physical, but, above all, in vital and mental, properties. Almost every system in quadrupeds is beneath his in structure. He is in every sense viewed by the physiologist or the metaphysician at the head of creation.—*Hufeland's Journal.*

British Hospital Report.

WESTMINSTER HOSPITAL.

Concussion—Premature Labour.

CASE I.—Martha Flood, a woman of middle age, coarse featured, so far advanced in pregnancy as to expect to be put to bed every day, was admitted September the 5th, 1833, into Anne's Ward, under Mr. Guthrie, about half-past eleven A.M. When she was brought in, she was in a state of complete insensibility, but exceedingly restless, throwing herself from side to side, and requiring several persons to keep her quiet in bed; the skin generally was cool, as likewise the scalp; pulse small and sharp; pupils not contracted, but insensible to the light; is reported to have vomited.

Those who brought her to the hospital, state that the preceding evening she fell down some steps into an ironmonger's yard, falling on her face; she became insensible immediately, and has continued so ever since; there was some bleeding from the nose. A surgeon was called in, who bled her, but they cannot say to what amount; finding she did not improve, he sent her here. She was ordered cold lotions to the head, and an injection immediately; the strait waistcoat applied, on account of her violence and restlessness.

Mr. Guthrie saw her at one P.M., and ordered her to be bled to fourteen ounces, the injection to be repeated, and purgatives to be employed, until the bowels were freely opened. He gave an unfavourable prognosis, and thought from her appearance that, previous to the accident, she must have been maniacal.

8 P.M. Castor-oil injections have been administered, and the bowels have since acted freely; she still continues insensible, with occasional stertorous breathing; continues very restless; pupils are rather more contractile; labour-pains commenced two hours since, at first paltry and grinding, but latterly sharp and almost incessant, according to the report of the nurse; the house-surgeon has just been summoned to the ward, and within a few minutes a girl, apparently lifeless, was born; no pulsation could be perceived at either fontanelle, but it continued, although feebly, in the cord, which was not tied, as hopes of preserving the child's life were entertained. Stimulation was at first attempted by *claquant les fesses*, which proving unavailing, brandy was rubbed on the face, at the suggestion of one of the dressers, previous to which the tracheal pipe was recommended. The brandy, however, proved successful, the child gradually reviving, at first sighing at intervals, which become less and less prolonged, and finally full respiration occurring, the cord was tied, and divided; the placenta came away soon after. The old women in the ward then took

charge of the infant, and were soon busily engaged, cramming it with sugar and butter.

6th. Is still delirious, but more rational, and the pupils are natural. She can answer questions, and says she suffers from headache; the pulse is full, strong, and frequent; bowels open by injections; there is no heat of scalp; ordered to be cupped to ζ xij. from the head, which, however, could not be effected, owing to her struggles; a few ounces only were obtained from the head and nucha, to which glasses were applied.

7th. She continues very restless, but is rather more sensible; pulse not so full. The child passed the night pretty well, but has been in convulsions the whole day, with a livid aspect; the warm-bath was tried in the afternoon with evident relief, but the child died in the evening.

8th. She passed the whole of yesterday (the 7th) in much the same state as before; in the middle of the day two dozen leeches were applied to the temples, and the same number again at night; they bled very freely, and she appeared much improved afterwards. She passed a much quieter night, and is now much more rational than she has been since she was admitted, answering questions sensibly, but unwillingly; complains of great pain in the head, and general soreness of the body; the pupils are natural; pulse moderate and regular, bowels open; no heat of scalp; tongue covered with a thin white coat of fur; no appearance of milk. Has had a blister to the epigastrium, and is now ordered one for the back of the neck.

9th. Another dozen of leeches were applied last night, but she has still pain in the head, and the scalp is hot, owing probably to her wearing a thick handkerchief round the head to conceal the barber's work, and her neglect of the cold lotions ordered; pulse rather smaller, and not frequent; is perfectly sensible; rather feverish, and she has had rigors; breasts swelled, and a slight secretion of milk has taken place; lochia abundant. The blister drew well.

11th. Complained last night of great pain in the head, and, as the pulse was then very strong, was bled to fourteen ounces, by which she was very much relieved; the pupils yesterday were rather dilated, but are now again contracting, and she is altogether improved, with the exception of that part of the face, where the effects of the fall were felt, there is considerable tumefaction and great tenderness; pulse moderate, soft, and regular, 80; tongue furred; bowels freely opened. A midwife, who has been to see her, has applied wetted paper to the breasts to repel the milk. Directed to have them drawn with a proper instrument.

12th. Continues to improve; put upon fish diet.

13th. Has very little pain; no bad symptoms.
15th. A small abscess, which had formed on the right ala nasi, opened.

20th. Nearly well.
22nd. Dismissed.

CASE II.—Concussion.—Mary Farley, æt. 12, admitted Sept. 30th, 1833, into Anne's Ward, under Mr. White, at 7, P.M., in consequence of having fallen about twelve feet in height from a ladder, about two hours previously. On admission she was cold and insensible; the head was shaved immediately, and the mark of a bruise discovered on the left parietal protuberance, where the skin was chafed, but not torn; no fracture could be discovered by the finger; total insensibility (is reported, however, to have spoken once or twice since admission); breathing stertorous; pupils not dilated, and they are slightly sensible to the stimulus of light; body generally cool; pulse small and slow. The stomach warmer has been applied, and bottles of hot water to the feet.

Oct. 1st. Reaction having taken place, twelve leeches were applied to the temples last night; has had a dose of aperient medicine, and cold lotions to the head, and was ordered an injection, if necessary; the stertorous breathing continued for some time after the application of the leeches, which bled well; she passed a tolerable night, and is now perfectly sensible; answers questions rationally; the bowels were freely opened by the aperient medicine, so that the enema was not administered; skin hot; face flushed; tongue furred; no headach; pulse full and quickened; pupils natural. Cont. lotio evaporans, et haust. cathart.

2nd. Doing well.
8th. Dismissed.

CASE III.—Concussion—Laceration of the Scalp.—Charles Boileau, æt. 25, was admitted the 16th of Oct., 1834, under Mr. Guthrie, into Mark's Ward. Sanguine temperament; of the middle size, and of robust make; a native of Paris, but long resident in England; an engine-turner by trade. According to his account, he was present at the fire which destroyed both Houses of Parliament, viewing it from Abingdon-street; on turning away to leave the spot, he received a blow from a policeman's staff, which felled him to the ground with such violence that he became insensible. He was picked up, and brought to the hospital; before he got there, however, he had recovered consciousness so far as to be able to take cognisance of passing events, but laboured under dizziness, and some confusion of intellect. On examination, a lacerated wound of an inch and a half in extent, over the left parietal bone, and another, not so long, but still deeper, on the left temple, were discovered. The latter was very jagged, and exposed the bone beneath; there were no marks of fracture. The symptoms of concussion gradually disappeared; the pupils were not dilated, and the pulse was of moderate power. The head

was immediately shaved, the man was sent to bed, and the wounds dressed.

Symptoms of inflammatory action and disorder of the head came on in the course of the next day, and continued with some severity, for a few days. General blood-letting, purgation, starvation, and quietude, were the remedial measures which were put in force, and, under this plan of treatment, relief was experienced. By the third day, suppuration was established in the wounds; the pus secreted by that on the forehead was not laudable, and the edges of the wound had a dirty, blackish appearance. The local treatment consisted in the application of poultices.

The suppuration continued abundant for some days, becoming of a healthy character, as the general health improved, granulations formed, and by the 9th of the following November, the wound on the parietal bone had healed; on the 14th he was dismissed cured, that on the temple having cicatrised without exfoliation from the exposed and apparently denuded bone.

CASE IV.—Concussion—Mania.—Samuel Charles Deacon, æt. 37, was admitted Nov. 17th, 1834, under Mr. Guthrie, into Northumberland Ward. A short time before he was admitted, while intoxicated, he slipped and fell, striking the head against the ground, lacerating the scalp just above the right frontal eminence, and exposing the bone; one or two other slight injuries to other parts were sustained. When brought in, he was labouring under symptoms of stupor, but could be roused by speaking to him rather loudly, relapsing directly into the same state; the pupils were not dilated, and there was no stertor. He was placed in bed, and the head shaved; about sixteen ounces of blood were taken from the arm, and a purgative administered, which acted, but with little relief to the symptoms. He continued in much the same state for the next few days, being rather more noisy and troublesome during the night, according to the report of the nurse, and requiring restraint. Venesection was again performed, and eighteen ounces of blood abstracted, with so much advantage, that under its influence, combined with that of active purgatives, the stupor gradually disappeared, leaving a state of mania, approaching even to idiocy, for which the only means then known of accounting was that it is an occasional sequence of concussion, in lieu, as it were, of phrenitis. The blood which was taken showed inflammatory marks.

He gradually recovered from the ill-effects of the concussion, but remained maniacal. The mystery was cleared up a day or two before he left the hospital, by some of his friends acknowledging that he had been in that state for many years. He was dismissed on the 6th of December.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, February 5, 1835:—Adolphus Taylor, —; John Gill, Stoke Courcy, Somersetshire; John Tuer, Leeds; John Llewellyn, Cowbridge, Glamorganshire; Geo. Robt. Van Freer, Enderby, Leicestershire; Francis Lovell, —.

MISCELLANY OF FACTS.

Embalming.—On the 6th of March last, Professor Franchina, of Palermo, embalmed a body in the anatomical theatre at Palermo. On the 14th of May, consequently more than two months afterwards, this new mummy was again examined in the presence of several hundred persons. The features of the deceased had undergone no alteration; the body was perfectly flexible; the flesh had the natural hue of death; but not the slightest smell of putrefaction was perceptible. The viscera, which, according to this new method, need not be removed, were well preserved, especially the lungs, which were found, on examination, in the most perfect state. The means employed by the Professor are not stated—indeed, it appears that he makes a secret of them. Larrey, the Surgeon-in-Chief of the French Army, employed for this purpose sublimate of mercury, which has lately been applied by Kyan to the prevention of the dry rot in timber. The body was laid in a solution of the sublimate, which was kept of equal strength, by small bags of the sublimate suspended in it. "I have myself seen," says Dr. Nürnberg, the writer of the article from which this paragraph is translated, "a body treated in this manner, which was carried through the New Mark (of Brandenburg), after the battle of Eylau, and which was in perfect preservation, but the bowels as well as the eyes, had been taken out." Franchina must therefore be acquainted with some other process.

We have again to record some splendid bequests:—The late Mrs. Temple, of the Circus, Bath, has bequeathed £1000 to the Bath General Hospital, and £100 to the United Hospital. The same lady has left the following sums to the underecited London charities:—£1000 to the Lambeth Female Orphan Asylum; £500 to the Asylum for the Indigent Blind; £500 to the Asylum for the Deaf and Dumb. The whole of these bequests are made free of legacy duty.

APPOINTMENTS.

Naval.—Mr. W. Gunn, assistant-surgeon of the Isis, to be surgeon. Mr. P. J. Pillmore, to be assistant-surgeon, and do duty at Haslar Hospital.

Military.—Assistant-Surgeon Russell, M.D., to the depot of the 76th Foot at Londonderry.

General.—Mr. Archer, surgeon of the Birmingham and Deritend Self-Supporting Dispensary. Mr. B. Blower, house-surgeon to the Northern Hospital, Liverpool.

Resignation.—Mr. J. A. Gillham, surgeon to the Royal Universal Infirmary for Children, Waterloo Bridge Road.

DEATHS.

At Dinapore, East Indies, Assistant-Surgeon W. Scott. At Cannanore, East Indies, Surgeon A. Patterson of the Medical Establishment. Mr. James Porter, surgeon, of Torry, Scotland. In Jamaica, Dr. Joseph Reay, formerly of Durham. Mr. William Kirk, of Girvan, Scotland, surgeon. Dr. J. S. Jefford, of Bradpole, near Bridport. Mr.

Sunderland, senior surgeon of the Halifax General Dispensary.

Deaths in the Army Medical Department last month.—Staff Surgeons Rogers and Stringer, h. p.; Surgeon Titford, h. p. 15th Garr. Bn.; Assistant-Surgeon Leslie, h. p. 45th Foot; Vet. Surgeons Gain, h. p. 9th Drag., and Shipp, h. p. 23rd Drag.

The London Anatomist. No. I. B. G. D. DEMOTT.
Spencer, on Ulcers of the Leg. 8vo.

CORRESPONDENTS.

T. B. shall hear from us by post in a day or two.

X. Z.—The circumstance he relates respecting the adulteration of drugs in various petty chemists' shops, shall at no great distance of time come under our consideration. X. Z. will see in the meantime that we have said a few words on the subject in our present.

A Lover of Truth.—We shall investigate the subject of his letter, and express our opinion in a future number.

Barbutus.—We should have inserted his letter, but we treat the party and his futile attacks with that contempt they merit.

Mr. G. has communicated to us an interesting case of puerperal fever. It occurred in a young woman who had been delivered of a fine child. The placenta was detained for many hours. On the fifth day a tumour of an oval shape was expelled from the uterus. Its structure consisted of a fibrinous mass, which was exceedingly vascular. On the 10th day after delivery she died. The uterus was large, and, as well as the contiguous peritoneum, was in a state of high inflammation. In the left corner of the uterus was a depression corresponding to the size and shape of the tumour; it was coated with a thick layer of a dark-coloured substance. This week the details cannot, we regret, be given.

LECTURES

INTRODUCTORY TO THE COURSE OF THE
INSTITUTES OF MEDICINE,

DELIVERED BY

ROBERT J. GRAVES, M.D.,

King's Professor, Dublin.

LECTURE XI.

GENTLEMEN,—Having spoken of longevity, the mean duration of human life, and the circumstances by which it is influenced, and having made some observations on population and the relative proportions of the sexes, I shall now proceed to the subject of temperament.

The ancients directed a considerable share of attention to this subject, and attributed great importance to a due knowledge of the different temperaments. They believed that the regulation of the economy in health, as well as the prognosis and treatment of disease, depended on an accurate acquaintance with their various modifications, and insisted strongly on the necessity of their study for the successful practice of the healing art. It may be proper to explain (though I do not deal much in definitions) that by temperaments we mean certain appearances of body, supposed to be connected with a peculiar state of health, digestion, temper, and conduct of the system when attacked by disease. You will find in Dr. Bostock's Physiology, that the ancients divided temperaments into four kinds, corresponding to the four qualities of Hippocrates, hot, cold, moist, and dry. These were supposed to give their specific characters to the four ingredients of which the blood was composed, namely, the red part, the phlegm, the yellow, and the black bile; and hence were derived the names of the sanguine, the phlegmatic, the choleric, and the melancholic temperaments, as indicating an excess of each of these substances. Dr. Bostock has endeavoured to reduce these to a better and more intelligible arrangement. He considers that the division of the ancients has some real foundation in nature, although on this, as on

other occasions, false theory has been blended with correct observation. To the four temperaments of Hippocrates, he adds a fifth, and, giving new appellations to the former, he ranges the leading varieties of the human constitution under five denominations, viz. the sanguine, the tonic, the relaxed, the muscular, and the nervous temperaments. He then goes on to describe each of these temperaments respectively, and concludes by observing, that although very few individuals possess any of these characteristics in an extreme degree, and though they may be considerably modified by circumstances, and confounded by intermixture, still we are warranted in believing that different temperaments actually exist, and that they influence the corporeal and mental functions of our frame.

According to all the definitions of temperaments, and among the rest those of Dr. Bostock (to whose account I refer you), you will find that it is not always from external appearances of the body, which a stranger could at once recognise, that a knowledge of any individual's temperament is to be obtained. In truth it does not appear to me to be possible, from any external appearances of body, to distinguish accurately either the ordinary state of health, or the probable issue of disease. We are taught to believe that those who are spare and dark complexioned, are most subject to bilious and abdominal complaints, and that persons of full habit and sanguineous temperament are liable to hæmorrhage, apoplexy, and other analogous morbid actions; while those who are of fair complexion, high colour, light hair, and blue eyes, are supposed to have a tendency to consumption. I do not believe that these observations are founded in fact. With respect to consumption, it is true that we meet with a great number of phthisical patients with fair complexions, red lips, and blue eyes, but then you are to recollect that the majority of the inhabitants of this country possess these characteristics. If you go into France or Italy, you will find consumption not less prevalent among the dark-complexioned, a fact easily accounted for by recollecting that in those countries the bulk of the population is dark and swarthy.

Again, as to the opinion that persons of dark complexion are more subject to abdominal diseases, I must observe that this does not correspond with my experience. While on the continent, where I received a considerable portion of my medical education, I was drilled into a thorough knowledge of temperaments, but I have never derived any particular advantage from this in the prognosis or management of disease.

Phrenologists have been at some pains in arranging temperaments, and have studied the subject for the purpose of enabling them to judge how far temperament may influence or modify the functions of the brain, and how far the quality as well as the quantity of brain are to be taken into account in the formation of individual character. I do not feel bound to enter upon any discussion connected with this subject, or to bring forward arguments against phrenology at the present day, when it is acknowledged by all scientific men, that it is only a species of ingenious empiricism founded on mere hypothetic induction. The admission that temperament should enter as a necessary ingredient into their calculations, is fatal to their system, for it is admitting the existence of a principle of which they can form no estimate. It matters not that one man's brain be of equal size and dimensions with that of another, if it be admitted that temperament exerts an influence on the nervous system of one which renders his brain far more energetic in the performance of its functions. Such an admission as this is quite sufficient to derange all their calculations. For my own part, I feel perfectly convinced that the quality of brain should be an essential element in our calculations, were we able to form an estimate of the mental powers from an examination of the cerebral mass.

Some of the appetites to which man is liable, and which are destined partly for the support of the individual, and partly for the propagation of the species, demand a brief notice. First, with respect to the appetite for food. I do not intend to enter into any general considerations relative to the phenomena and theory of the process of digestion, my purpose, at present, is merely to state a few facts concerning the appetite for food. This instinctive desire, though manifested at the very earliest period of extra-uterine life, does not appear to exist in the fœtus during the whole time of its sojourn in the uterus, but, during the last two months of utero-gestation, the stomach is so prepared, that, if expulsion should occur, the fœtus is capable of commencing the process of digestion. At this period, the food by which the young of most of the higher classes of animals is nourished, consists of a bland emulsion prepared by the hand of nature, and composed of oily, saccharine, caseous, and albuminous ingredients, blended with inimitable art, so as to form a highly nutritious and digestible aliment, not requiring the aid of teeth for mastication, or of saliva for deglutition. From the

facility with which it is digested, and the large quantity of nutriment which it contains, assimilation goes on with great rapidity, and thus a sufficient quantity of materials is furnished to supply the wants of the growing body. When we come to the subject of animal chemistry, I shall examine the composition of milk in detail, for the present I shall only remark (and the fact is of great importance in many points of view) that the aliment destined for the nutrition of all the higher animals during the tenderest and most delicate stage of post-fœtal life, is not a simple, but a compound substance. In birds, the food of the young is the same as that of the parent, but it is generally prepared by some previous act on the part of the parent, who either breaks it up, so as to render it more easily swallowed, or by taking it into the crop, reduces it to a pulpy state, in which it is returned for the support of the young bird.

Prompted by instinct, the infant immediately after birth seeks the food best suited to its wants, and, when placed near the breast, proceeds at once to gratify this earliest of propensities. There is nothing more curious or interesting in the history and phenomena of animal life, than the remarkable discrimination, and almost unerring tact, manifested by animals in the selection of food. I have already alluded to this subject, and mentioned that animals almost invariably choose the food which is proper for them, nevertheless, they sometimes commit mistakes, particularly when impelled by strong instinctive impulses. Thus cows and horses, after long confinement in stables, and dry feeding, are apt, when first turned out into green pastures, to devour the fresh herbage so greedily, that they frequently swallow plants which they would have rejected at another time, and in this way are sometimes poisoned. Linnæus pointed out this circumstance long ago, and remarked that, at Tornea, cows, on being allowed to go into fresh pastures at the beginning of spring, appeared to have lost the instinct which, under ordinary circumstances, prevents them from eating the water hemlock, and other poisonous plants. Dr. Fleming mentions that, in the Orkneys, goslings, when first turned out in spring, frequently die from eating the leaves of the fox-glove.

In man, the instinct which leads to the selection of appropriate food, is by no means so accurate as in animals; in the earlier periods of life the selection of food depends upon the parent, after this it is regulated, not by instinct, but by reason and experience. With respect to the peculiar sensation termed hunger, it is not necessary that I should enter into any detailed investigation of its cause, particularly as our knowledge on this point is both scanty and imperfect. By some it is attributed to the friction of the coats of the stomach on each other in the empty state of that organ; others look upon it as a consequence of the irritation produced by the accumulation of the gastric

juice in contact with, and acting on, its coats. Various other explanations of this phenomenon have been given, some of which are trifling, and all unsatisfactory. It would appear to arise from the sympathy which the stomach has with the whole system, as proved by the fact that in cases of disease of the pylorus, where assimilation does not take place to any extent, the patient may feel very hungry with a full stomach.

Where a supply of proper food cannot be obtained, various modes have been resorted to for relieving the sensation of hunger. Some persons allay the cravings of appetite by chewing tobacco and swallowing part of the saliva, others by smoking, and it is a fact well known to most nations, particularly the Irish, that the want of a breakfast may be less sensibly felt by the use of the pipe. Soldiers on long marches have been frequently known to seek for an alleviation of this sensation by holding pebbles in their mouths, and in many parts of the East the same thing is more completely accomplished by eating opium. Some of the native tribes in South America, whose supply of food is scanty and precarious, prepare a kind of aluminous clay, which they make up into balls, and swallow when pressed by famine. Many of the Hottentot tribes, and several individuals of other countries, who travel through the inland parts of Africa for the purposes of commerce or scientific investigation, carry with them what are termed famine girdles, these are worn over the loins and abdomen, and are tightened accordingly as their supply of food fails, experience having taught them that compression of the abdominal viscera is one of the most effectual modes of relieving the sensations of hunger.

With regard to the quantity of food which an individual is capable of consuming at a meal, this is chiefly regulated by habit. Europeans and most civilised nations who are accustomed to live regularly eat at certain times, and take a certain proportion of food, and if they should chance to exceed this they experience a sense of oppression about the stomach, and feel heavy and incapable of exertion. Among savage tribes, however, where agriculture and commerce are either totally neglected or but very imperfectly pursued, the supply of food depending on the uncertain labours of the chase, and the prey being frequently killed at a distance from home, a habit of devouring immense quantities of food is generated, and the savage, doubtful of the prospect for the next few days, concludes that the best and simplest plan he can pursue is to eat as much at once as will probably do until another chance of supplying his wants may occur. Thus it is related by a missionary in his Travels through Southern Africa, that on one occasion his party had been forced to tighten their famine girdles to the utmost, having been for several days without any kind of solid food, when fortunately a zebra was shot. The carcase was immediately

roasted, and, after he had eaten two or three pounds, he felt an inclination to sleep, and lay down at a distance from the party. During the course of the night he awoke, and found that the negroes were still engaged in stuffing themselves with unabated eagerness. He again went asleep and again awoke, and continued in this way, alternately dosing and waking, during the night, but remarked, with no small degree of astonishment, that every time he awoke the Africans were still eating away as if they had only just commenced. They had heaped fresh fuel on the fire, and taken off their famine girdles in the beginning of the night, and they lay stretched on the grass, gorging themselves until their bellies, which had been quite lank and concave, became strikingly protuberant and convex.

Capt. Cochrane, in his Journey through Russia and Siberia, relates the following facts, strongly illustrative of the influence which habit, climate, and hereditary disposition, exercise upon the human appetite and digestive powers. "At Tabalak I had a pretty good specimen of the appetite of a child, whose age did not exceed five years. I had observed the child crawling on the floor, and scraping up with its thumb the tallow-grease which fell from a lighted candle, and I inquired in surprise whether it proceeded from hunger or from liking of the fat. I was told from neither, but simply from the habit, in both Yakuti and Tongousi, of eating whenever there is food, and never permitting anything that can be eaten to be lost. I gave the child a candle, made of the most impure tallow, a second, and a third, and all were devoured with avidity. The steersman then gave him several pounds of sour frozen butter; this he also immediately consumed; lastly, also a large piece of yellow soap; all went the same road, but as I was convinced that the child would continue to gorge as long as it could receive anything, I begged my companion to desist as I had done.

"As to the statement of what a man can or will eat, either as to quality or quantity, I am afraid it would be quite incredible; in fact, there is nothing in the way of fish or meat, from whatever animal, however putrid or unwholesome, but they will devour with impunity, and the quantity only varies with what they can get. I have repeatedly seen a Yakuti or a Tongousi devour forty pounds of meat in a day; the effect is very observable upon them, for from thin and meagre looking men they will become perfectly pot-bellied. Their stomachs must be differently formed from ours, or it would be impossible for them to drink off at a draught their tea and soup scalding hot without the least inconvenience. I have seen three of these gluttons consume a rein-deer at one meal; nor are they nice as to the choice of parts, nothing being lost, not even the contents of the bowels, which, with the aid of fat and blood, are converted into black puddings."

Perhaps, gentlemen, you may be inclined to look upon this statement as grossly exaggerated; I do not believe it to be so, for it is fully corroborated by the following, taken from the narrative of the voyage made by the Russian Admiral Saritcheff.

"No sooner," says the Admiral, "had they stopped to rest and spend the night, than they had their kettle on the fire, which they never left until they pursued their journey, spending the intervals for rest in eating, and, in consequence of not sleeping, they were drowsy all the next day. Such an extraordinary voracity was never attended with any ill effects, although they made a practice of devouring at one meal what would have killed any other person. The labourers had an allowance of four poods (one hundred and forty-four pounds English) of fat, and seventy-two pounds of rye flour, yet in a fortnight they complained of having nothing to eat. Not crediting the fact, the Yakuti said that one of them was accustomed to consume at home, in the space of twenty-four hours, the hind quarter of a large ox, twenty pounds of fat, and a proportionate quantity of melted butter for his drink." The appearance of the man not justifying his assertion, the admiral had a mind to try his gormandising powers, and for that purpose he had a thick porridge of rice boiled down with three pounds of butter, weighing together twenty-eight pounds, and although the glutton had already breakfasted, yet did he sit down to it with the greatest eagerness, and consumed the whole without stirring from the spot; and except that his stomach betrayed more than ordinary fullness, he showed no sign of inconvenience or injury, and would have been ready to renew his gluttony the following day.

An instance of extraordinary appetite has been lately communicated to me by Mr. Mulock. A gentleman affected with psoas abscess, which opened in the usual manner, was greatly emaciated in consequence of the excessive discharge of purulent matter. He had all the symptoms of violent hectic, and was sinking rapidly, when, being given over by the late Mr. Hewson, he determined to gratify his desire for food, which had shortly before become inordinate. He accordingly took six meals in the day, consisting of beef-steaks, mutton, fowl, and, in short, of food the most nutritious, washed down with plentiful potations of wine and the strongest porter. Mr. Mulock, who watched the case very carefully, found that he consumed on an average sixteen pounds of solid food daily. The effects of this diet on his constitutional symptoms were very remarkable. His pulse became gradually slower and fuller, his strength increased, the colliquative sweats diminished, and he finally recovered perfectly. This and similar instances are full of instruction, and prove that fever may be a consequence of debility. The effects of a properly adjusted diet in diminishing fever of this

nature, I every day witness in the fever at present epidemic, *in the more advanced stages of which raving, very quick pulse, want of sleep, and a host of bad symptoms, often yield to wine and proper nourishment.*

Mr. Derwent Conway, in his "Personal Narrative of a Journey through Norway," makes the following remarks, well worthy of the attention both of the physiologist and the practical physician.

"In looking at the Norwegian peasantry, one is struck with their sturdy forms and healthy faces; notwithstanding the great appetites and daintiness of the Norwegians, and the artificial style of cookery practised among them, indigestion, with its train of evils, is unknown among them. I leave it to the physiologist to determine whether this be owing to acquired habit, or to constant exercise, or to peculiarities of climate; it is certain, however, that the traveller will in vain search the interior of Norway for a dyspeptic, and yet I am well convinced that the diet of a hearty Norwegian would create such an attack of indigestion in any inhabitant of my own country, as would put him on a regimen of water gruel for a month. In looking at a healthy population such as Norway, where diet is not more simple than it is in England, and excess in eating and drinking is far more general, we are led to conclude *that works on diet and regimen are less useful than they pretend to be*, and that we must look for the differences in health rather to certain refinements, luxurious indulgences, incident to a highly civilised state of society, than to the errors of diet. This may at least apply to the upper ranks. I am certain that one may see a greater number of *malades* in the city of Bath in one day than could be collected from every part of Norway. But if we were to transport a hundred of the inhabitants of Asterdalm to the gaieties of a London winter, with its refinements and artificial habits, though to quite as simple a diet, the change would soon make itself apparent in the enervated frame and languid faces of the Asterdalms. The converse of this I know to be true. I am well acquainted with a person, who in this island was a martyr to indigestion; nothing but the simplest kind of food could be eaten by her for years, and during all that time not one particle of butter had been tasted. But not many months after a removal to Norway, there was not a trace of dyspepsy left; she ate the same diet, and almost as much, as those among whom she had come, but along with this was coupled Norwegian habits, early rising, early hours, daily and nearly constant exercise in the open air."

Indeed, gentlemen, I have long been of opinion with Mr. Conway, that works upon diet are less useful than they pretend to be. I am in the habit of considering the stomach rather as a joint sufferer with the rest of the system, than as the cause of the disease itself.

Physicians in general are too much inclined to look upon those cases in which digestion is badly performed, as cases of mere disease on the part of the stomach, whereas, in the majority of instances, the stomach only participates in the effects produced by some cause which has debilitated the system in general, and consequently has weakened the powers of the stomach as well as those of the other organs. Loss of blood, mental anxiety, constant confinement and want of exercise, over exertion of mind, late hours, excesses in sensual enjoyments; these, and a thousand other causes, give rise to general debility, to an enervated state of the whole frame, including all the organs, the stomach among the rest. When such a result has been produced, how mistaken and narrow the views of those who only look to the state of the digestive organs, and who attribute to their derangement the origin of all the evils that afflict the patient! How unsuccessful must be their practice, who in such cases confine their attention to accurate rules of diet, and to medicines calculated merely to act upon the stomach and liver; how frequently, overlooking the true sources of the malady, do they aggravate the patient's suffering by the blue pill and purgative system! A man may have a stomach weakened in consequence of his suffering from peritonitis, which prevents sleep; his powers of digestion may be impaired in consequence of the reaction produced on the constitution by various local diseases, piles, cancer, ulcers, or by various general affections, as gout, syphilis, scurvy. It is obvious that in all such cases the indications for cure must be very different, and must extend beyond the mere rules of diet, or the selection of aperient and stomachic remedies.

I may remark, that, in some persons, there exists a ravenous and insatiable craving for food, constituting the disease termed bulimia. Something of this nature occurs in patients labouring under diabetes, they eat and drink both night and day, and hence they are by far the most expensive inmates of an hospital. In Dr. Thomas's Practice of Physic you will find some curious cases of bulimia detailed; among the rest is one of a person, named Tararre, who had recourse to the vilest filth to satisfy the cravings of an insatiable appetite, and who, among other things, was strongly suspected of having eaten a child. It may be observed here, that in such cases the functions are never natural. The discharges from the bowels and bladder are inordinate in quantity, and remarkable for their unnatural character, and there is an enormous evaporation of fluid from the skin, generally of a highly offensive odour. A singular species of bulimia exists among the West Indian blacks, and has been very well described in the *Edinburgh Medical and Surgical Journal*. Persons labouring under this affection have a desire to eat lime, ashes, earth, and other disgusting substances; the

disease is generally accompanied by a hard and tumefied state of the abdomen, and in some instances appears to be of an epidemic character. In chlorotic and hysteric women something analogous to this is frequently observed, the appetite for food becomes diseased and they devour various indigestible and improper substances. I have this day visited a young lady, who has manifested a strong desire for eating clay.

In some cases, on the contrary, the appetite for food becomes preternaturally diminished, and it is astonishing to think of the small quantity of aliment on which some individuals have existed for a great length of time. Instances are brought forward as wonders, of persons, particularly females, having subsisted for a considerable period without any food at all. You will sometimes hear of instances of young ladies having lived for months on such meagre aliment as lemon-juice. Thus Johanna Naunton is said to have lived on lemon-juice alone for seventy-eight days*.

I may, however, observe, *en passant*, that most cases of this description occur in the persons of hysterical females; and it is a curious fact, that some individuals have an extraordinary tendency to deceive their friends and medical attendants. Weak-minded persons of an hysterical habit, led away by an inordinate desire to cause pity and wonder, seek to become the subjects of some surprising story or miracle; and it is astonishing to see what inconveniences they will undergo in order to excite this temporary interest. Among the various modes adopted for accomplishing this, fasting is one of those most generally employed; and hence we frequently hear of females who have lived for months without taking any food. Cases of this description, and other instances of an analogous nature, are curious circumstances as connected with the strong tendency which exists in mankind to deceive and be deceived. A case is recorded by Dr. Otto of Copenhagen, in which it is stated, that needles to the amount of four or five hundred were extracted at various times from the arms and body of a female. This case was published in all the Medical Journals of Europe, and excited a great deal of attention, and certainly it must be acknowledged that this female succeeded completely in her purpose, for it appeared, on accurate investigation, that she thrust the needles into various parts of her own body for the purpose of exciting wonder and having herself talked of. I recollect a case somewhat like this, which occurred in the Female Orphan House in this city. One of the girls was attacked with inflammation of the fore-arm, and the symptoms were so violent that all treatment proved unavailing. Deep-seated inflammation of an intense cha-

* In Caillet's Account of a Residence among some African Tribes, the natives are represented as subsisting *almost altogether upon milk*.

rafter attacked the sheaths of the muscles and the tendinous expansions, and sloughing went on to such an extent, that the surgeon who attended the Institution finding the best-directed efforts of treatment unavailing, came to the resolution of amputating the arm. The operation was performed, and, on examining the limb, a vast quantity of needles were found in various parts, thrust deeply into the muscular mass which forms the bulk of the forearm. A case, still more extraordinary, is related in the Transactions of the Association of the King and Queen's College of Physicians in Ireland: it was that of a young woman from the South of Ireland, who was said to have vomited up the larvæ of several insects; indeed, it was stated by some physicians in Cork, on whom she had imposed, that she had discharged a winged insect, which, if it did not fly out of her mouth, was at least perfect in all its parts when ejected from her stomach! This extraordinary narrative, now ascertained to have been the result of gross but well-managed deception, has been frequently quoted by Continental writers, and has been suffered, uncontradicted, to disgrace the excellent work in which it was originally published! A case is also published of a woman who did not pass a single drop of urine for five months!

It is astonishing what pleasure persons of this description find in deceiving their friends, and what ingenuity they practise to support the deception. It is necessary for every practitioner to bear this in mind, for you can have no idea of the frequency with which attempts to impose, in a minor degree, occur among private families, and how often the friends of hysterical and hypochondriac individuals are thrown into a state of alarm by such practices. Again; such impositions frequently deceive the medical practitioner; and when detected, as they generally are, by accident or by the keener penetration of non-professional persons, they have a tendency to throw ridicule on the profession. I remember being brought, some time ago, by a medical friend, to see a woman, living at one of the gate-houses in the Phoenix Park, who was said to have passed the most extraordinary substance from the bowels. I procured some of the alvine discharges, and had the curiosity to go through the dirty task of lixiviating it, and insulating from the fecal mass the foreign substances blended with it. I found these to consist entirely of a quantity of gravel, which the impostor had picked up in one of the walks and secretly mixed with the fæces. Some of the larger quartz pebbles had been selected by the physician in attendance, who had them washed and preserved as specimens of gall-stones!

But to return;—without adducing examples of hysteric females, it may be stated that the greatest length of time which persons in ordinary health can live without taking any food, appears, from the most authentic accounts, to be about seven or eight days. Thus we find, in Franklin's account of his Journey, that Dr.

Drummond's brother lived for seven days without food (and this is generally the utmost length that total abstinence can be borne without producing fatal consequences). There is, however, one case on record of a person who survived until the eighteenth day. Such cases must be exceedingly rare, for in the normal condition of the system no human being can live without food longer than from seven to nine or ten days. Many of the inferior animals, as toads, serpents, tortoises, and insects during the chrysalis state, subsist for a considerable length of time without taking any kind of aliment, and the same thing may be observed in hibernating animals. In the latter, the suppressed state of the vital energy during the dormant period, and the very imperfect discharge of all the functions, seem to be the chief reason why their prolonged abstinence is borne with such remarkable impunity.

Long fasting, besides its immediate effects in reducing the bodily powers to a state of great debility, has a strong tendency to bring on a peculiar state of the system, in which the stimulus of food is apt to produce fatal effects by lighting up rapid and violent inflammation. Persons who, after long deprivation of food, have taken a hearty meal, very seldom recover from its effects. The same thing is to be observed of drinking a quantity of fluid after a long continued thirst. Thus Columbus states that several Indians who had been confined in his vessel and deprived of drink for several days, died almost immediately after swallowing a copious draught of water.

It is highly instructive to the practical physician as well as the enquiring physiologist; to consider what is the nature of those symptoms which arise from want of food, when continued beyond a certain period. I need not describe the sensation of distress and sinking, the total prostration of bodily power, the burning thirst, the strange type of fever, and the maniacal excitement produced by deprivation of food. You will find the effects of starvation depicted in all their appalling reality in the accounts given by many authors.

A few of the facts connected with symptoms of starvation, however, are in one point of view highly interesting, and demand a more particular notice. In the first place, continued deprivation of food produces (and this is a very singular effect) inflammation of the stomach. After some time this is followed by fever, and then furious delirium. Of these three important facts the latter is the most curious. In all cases of starvation one of the most invariable consequences has been *the occurrence of high maniacal excitement*. It is necessary to bear this in mind, because a knowledge of the fact enables us to look with a different eye on the apparently savage and demoniac acts of those poor wretches, who have been exposed to the horrors of starvation. In reading the sickening details of the wreck of the Medusa, it is some consolation to reflect

that the murders and atrocities, committed by the crew, were probably not the acts of accountable beings, but the ordinary results of maniacal excitement.

The following particulars, taken from a narrative of the sufferings of those who embarked on the raft, constructed to save the crew of the French frigate, the *Medusa*, presents strong proofs of the excitement of the delirium caused by starvation:—

“The second night was still more dreadful, and many were washed off into the sea, although the crew had so crowded together, that some were smothered by the mere pressure. To sooth their last moments the soldiers drunk immoderately, and in their fury attempted to cut the cables which held together the spars and beams of the raft; a general conflict ensued between those who attacked and those who defended it. Many of the former were killed, and one, who affected to rest himself upon the side, but who in fact was treacherously cutting the ropes, was thrown into the sea. Another, whom M. Correard had snatched from the waves, turned traitor a second time, he too was killed. At length the revolvers, who were chiefly soldiers, being repulsed, threw themselves on their knees, and with the utmost abjectness implored mercy; at midnight, however, they rebelled again. Those who had no arms fought with their teeth, and thus it was that many severe wounds were inflicted; one man in particular was most wantonly and dreadfully bitten above the heel, while his companions were beating him on the head with their carabines, previously to their throwing him into the sea. The raft was strewed with dead bodies, after innumerable instances of treachery and cruelty, and from 60 to 65 perished that night. The force and courage of the strongest began to yield to their misfortunes, and even the most resolute laboured under mental derangement. In the conflict the revolted had thrown two casks of wine into the sea, together with all the remaining water. A day of comparative tranquillity now succeeded. The survivors erected their mast again, which had been wantonly cut down in the battle of the night, and endeavoured to catch some fish, but in vain; then it was that they were reduced to the last resource, the most repugnant to human nature, and the bodies of their dead companions became their sustenance. A third night followed, which was only interrupted by the plaintive cries of wretches, exposed to every kind of suffering, ten or twelve of whom died of want. Some flying-fish were caught, which, mixed up with human flesh, afforded one scanty meal. A new insurrection, still for the insane purpose of destroying the raft, broke out on the fourth night, and this too was marked by perfidy, and terminated in blood; most of the rebels were thrown into the sea. The fifth morning mustered but thirty men alive, and these in the most wretched state, sick and wounded, and the skin of the lower extremities corroded

by salt water. * * * There now remained but twenty-seven; of these but fifteen appeared capable of out-living their present fatigue. A council of war was held, and it was resolved that, as the weak consumed a part of the common store without hope of surviving, they should be thrown into the sea. * * * In such a situation, distress and misery increased with a very accelerated ratio; and even after the desperate measure of destroying their companions and eating the most nauseous aliments, the surviving fifteen could not hope for more than a few days' existence. A butterfly lighted on their sail the ninth day, and though it was held to be the harbinger of good many a greedy eye was cast upon it. The misery of the survivors increased, and they even stole from each other little goblets of urine, which had been set to cool in the sea-water, and which was now considered a luxury.” M. Savary made some observations on this subject which are not devoid of interest, particularly when we combine them with the diuretic qualities lately ascribed to urea. He says that the urine of some was much more agreeable than that of others, and in all cases this beverage proved an instantaneous and powerful diuretic.

A curious fact connected with this subject is mentioned by Captain Cochrane, who says, “that nothing is so acceptable to rein-deer as human urine, and I have even seen them run to get it as occasion offered*.”

In modern times, national famines are of much less frequent occurrence than during the middle ages, when commerce was restricted and agricultural pursuits insecure. The greatest famine we ever experienced in England was in the reign of Edward II., in 1513, but even its horrors and devastations were exceeded by those which marked the occurrence of similar misfortunes in France, where, in 1031, under Robert, human flesh was sold in the butchers' shops.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XIX.

Labour.

GENTLEMEN,—We now come to the consideration of that process by which nature completes the great work of development in which she had been engaged for nine months previously, and by which she ushers into the

* Journey through Russia and Siberian Tartary.

world the new being, freed from the confinement of its mother's womb, and capable of prolonging that existence, the commencement of which has been involved in so much mystery. When we investigate the powers which are brought into action, and consider the changes which must necessarily take place for this purpose, the beautiful proportion of the passages to the body which has to be conveyed through them, and of the expelling powers to the resistance produced by it, we cannot but be struck with the evidences of benevolent design and adaptation which have thus been displayed, in rendering the process of parturition safe and healthy, which is apparently fraught with so much danger both to the mother and her child.

For the purpose of taking a clear and simple view of it, labour has been usually divided into periods or stages; by this means we are also able to refer to any part which we may be desirous of noticing. In the English schools, labour has generally been divided into three stages, the *first*, from the commencement of the pains to the full dilatation of the os uteri; the *second* commences when the os uteri is fully dilated, and terminates with the birth of the child; the *third* terminates in the expulsion of the placenta. In the schools of Germany, labour has been divided into five stages, and, although I am averse to any multiplication of arbitrary divisions, yet, as I think that this division not only assists in forming a more correct idea of the process of parturition, but is also more applicable in a practical point of view, I shall adopt it in the present lecture.

The *first stage* begins with the first perceptible contractions of the uterus; these have no effect upon the os uteri, and may continue two or four days, and, in some cases, may even last a whole fortnight, before actual labour commences. Properly speaking, they are not positive pains, but rather communicate a sensation of equable pressure round the abdomen. The uterus feels for a time hard and tense, and, in a state of health, they are accompanied by no pain, but merely by a sense of tightness or pressure; nevertheless, in a rheumatic habit, much actual suffering is occasionally produced; from preceding the commencement of real labour they have been called the *dolores presagientes*. "The first contractions are feeble, and communicate no sensation to the patient; in order to discover them, we must place our hand upon the abdomen, if we feel the globe of the uterus raise itself and become hard, this is a true contraction. These contractions gradually increase until they excite pain, but pain is not essential to a contraction; it depends on the distension and compression of the nerves, produced by the resistance of the body upon which the uterus acts, and increases in severity in proportion to the degree of resistance and contraction*." These pains generally

appear towards evening, and go off again as night advances.

The patient experiences repeated calls to pass water; there is a degree of restlessness and anxiety about her; she is never able to sit still or continue long in the same posture. In primiparæ, on examination per vaginam, you will not be able to reach the os uteri easily at this moment, it will be found high up in the hollow of the sacrum, forming a small circular depression, through which not even the tip of the finger can pass, being closed up with a plug of gelatinous matter. The head will be felt deep in the cavity of the pelvis, pushing the anterior portion of the inferior segment of the uterus before it.

In women who have already had children, the os uteri is neither so high up, nor so far backwards towards the sacrum; a small portion of the portio vaginalis of the cervix is still remaining, the os tinæ, or os uteri externum, is more or less open, and its edge uneven, thick, and somewhat hard in places from cicatrices, the result of former labours. In primiparæ, when the os uteri first begins to open, its edge is generally thin, sometimes so much so, as even to resemble thin parchment. By degrees it swells, becomes soft, and more capable of dilatation; it is warm, and continues slightly tense during the interval of the pains. "When the os uteri *does* dilate, it is not by its edges being stretched mechanically, it is by an absolute loss of power to maintain longer a state of contraction*." The vagina swells and becomes soft, followed by a copious secretion of inodorous mucus; the more albuminous it is the better, and it is always a good sign when lumps of albuminous matter come away from time to time; the thicker, softer, and more cushiony the os uteri is, the more mucus it secretes; its fibres being now more separated from each other than when it was thin, it becomes much more dilatable. Besides the lubrication of the vagina, this secretion of mucus before labour acts as a topical depletion to the neck of the uterus, vagina, and perinæum, and thus greatly facilitates their relaxation. This secretion is of great importance in promoting the healthy progress of labour, nor can you sufficiently estimate its value, unless you are aware of the consequences arising from its deficiency or absence. By frequent or incautious touching the glands, furnishing this discharge, are over stimulated and become inflamed, the secretion immediately ceases, the parts become hot, swollen, and tender, especially the mouth of the uterus if not fully dilated; the pains will become less frequent and less protrusive; the woman becomes restless, and enjoys no calm in the intervals of the pains; fever is excited, headach, thirst, and a hot skin follow; in a word, a new condition of the system arises, which almost supersedes the business of labour. It would be in vain under such circumstances to offer a

* Leroux.

* Dewees.

substitute for the lost mucous secretion by presenting to the part any unctuous or mucilaginous substance whatever; it can only be recalled by rest and free blood-letting*.”

As soon as the os uteri in primiparæ begins to open, or, in those who have already borne children, to be dilated, the *second stage of labour commences*.

The patient is now no longer able to conceal her pains when they come on. If she be walking about, she is obliged to stand still and catch hold of any thing within reach, or support herself by leaning against a chair, &c., until the pain has ceased. The pains are situated chiefly in the loins, not, as many works on midwifery say, extending from the fundus uteri down to the thighs. “In women,” says Wigand, “who have already borne children, the os uteri is at this moment much lower than in primiparæ; it is thick, soft, and cushiony, communicating to the finger a spongy feel. It is cool, hanging quite relaxed during the intervals of the pains, and so yielding, that two or more fingers can pass. The thin hard distended os uteri, at the beginning of labour, exerts a much greater resistance against the head than when it becomes thick and swollen, for, in the latter case, the fibres being separated from each other by the swelling, it becomes more dilatable.” During the intervals of the pains the fundus and other parts of the uterus upon external examination become softer and more compressible, the different parts of the child and its movements are to be felt, both externally as well as internally, more distinctly; the patient is free from pain, and feels herself in an agreeable state of quiet, which is frequently accompanied by a short refreshing sleep. The os uteri, which has become somewhat larger during the last pain, is soft and loose, so much so, that you may move it about with the finger; the presenting part of the child is now more moveable. The membranes, which had been distended and thrust down into the vagina by the liquor amnii, become loose, and retreat more or less into the cavity of the uterus, but immediately as the pain comes on, the os uteri becomes tense and hard, the whole uterus becomes hard, and the parts of the child which, during the intervals of the pain, were to be felt externally, now become indistinct; if the os uteri be thin, it will now feel so tightly stretched as to make you think it would rupture with the slightest violence, especially if little or no liquor amnii has collected before the head, which is now forcibly pressed upon it, or still more so if the membranes by any cause have been prematurely ruptured. If a quantity of liquor amnii has collected between the presenting part and the membranes, these become distended into a tight bag, which presses against the os uteri, and which, by the equable pressure which it exerts upon it during a pain, greatly facilitates its early

dilatation; in this manner the os uteri gradually attains its full degree of dilatation viz. to about two inches and a half in diameter, and when this is the case we may expect the membranes to rupture with every pain. At this point the second stage terminates.

The contractions of the uterus during these two first stages do not appear to be directed so much towards the expulsion of the child, but rather to *prepare* it, as well as the passages, for this purpose, by gradually arranging and regulating the different forces, and at the same time by giving such a position to the child, and such a degree of dilatation to the os uteri, as may ensure its passage with the greatest facility and certainty; they have been therefore called the *dolores preparantes*.

Upon examination, we find streaks of blood mixed with the mucus, which adheres to the finger, and this is considered as a proof of the os uteri being fully dilated; this appearance of blood has been called by the midwives a *show*, and is produced in part by a separation of the chorion from the edge of the os uteri, which therefore bleeds; at this moment a violent rigor or shivering is frequently observed, but it differs considerably from the common shivering which is produced by cold, in not being capable of being relieved by external warmth, and the patient will not unfrequently express her surprise that she should shiver thus violently and yet feel quite warm; it is a convulsive affection resulting from nervous sympathy between the muscles of the face and other parts of the body and the os uteri upon its having reached its full degree of dilatation.

The *third stage of labour* begins with the full dilatation of the os uteri and the rupture of the membranes; it is a remarkable fact, but you will find that the woman loses her patience more in the second stage than in the third, although in this latter stage the pains are much stronger and more severe; in the second stage the pain is chiefly confined to one spot in the loins, she has not become accustomed to the endurance of it, nor is she comforted with the feeling that it has been of any assistance to her, or that the progress of her labour has been at all advanced by it; but when the membranes have ruptured, a considerable change in the character of the pains follows; although more severe, they are nevertheless much more tolerable, the escape of the liquor amnii shows also that some real advance has taken place, and encourages her to bear her sufferings with patience and resolution.

These pains, gentlemen, are the *dolores ad partum proprii*, the real genuine pains of labour, for by their action is the presenting part compelled to quit the uterus and enter the vagina; the os uteri has disappeared entirely, so that the vagina and cervix uteri form one continuous passage; not unfrequently, however, its anterior lip dilates

* Dewees.

slowly, more especially in primiparæ, where the head at the beginning of labour has been situated so very low in the pelvis, and it will occasionally depend so considerably, as even to be felt between the labia; any attempts to force it up above the head are of no avail, they only tend to inflame the parts and make them swell; with a little patience it will gradually disappear of itself: those who suppose they can force up the anterior lip of the os uteri above the head under these circumstances, deceive themselves in their examination, or if it does actually yield, it is because the part itself would, in the course of a pain or two, have gone up spontaneously.

The sutures will now be felt riding over each other, and the fontanelles much diminished in size, and from the degree of pressure to which the head of the child is subjected, it becomes considerably elongated, and an œdematous swelling of the scalp forms upon the presenting part. The moment the head has cleared the os uteri and entered the vagina, the contractions of this canal not only become more powerful and of longer duration, but now also the abdominal muscles are called into action, and the vehement efforts which characterise the *fourth stage of labour* commence. We never see the really powerful straining pains come on (the head may be never so low in the pelvis) so long as the os uteri is not sufficiently dilated; the sympathetic connexion between the vagina and abdominal muscles is precisely the same as between them and the rectum; the moment the vagina becomes distended it begins to contract upon the distending body, and, like the rectum, excites the abdominal muscles to strong and involuntary action. This evidently does not depend upon the state of the os uteri, for in cases where this is pushed very low and yet not much dilated, the patient feels no impulse to strain, nor do these involuntary straining efforts depend upon the rectum being pressed upon by the head, as some have imagined, because in primiparæ we find that the head frequently occupies the cavity of the pelvis for some time before labour comes on. She wishes for the next pain, and yet dreads it; the face becomes red, swollen, and bathed in perspiration, her expression is hurried, her eyes are wild, and when a pain comes on she cries out in spite of any previous determination to the contrary; and I have known well educated females, women of strong mind, who had previously determined to be perfectly reasonable and quiet during these moments, but who nevertheless, when the time came, were irresistibly compelled to scream out; the face sometimes changes its expression surprisingly, so much so, that even her own attendants would scarcely recognise her; the pains increase, and the head now begins to be firmly pressed against the perinæum. During the pain no liquor amnii is discharged, nor also does it escape during the intervals, although

the works on midwifery assert that it does; the fact is, it escapes just at the moment when the pain is coming on or going off. The reason for this is obvious; during a full contraction of the uterus, the head is so firmly pressed against the soft parts as effectually to plug up the vagina; when the pain ceases entirely, the pressure upon the contents of the uterus ceases, and therefore there is nothing acting to expel it, hence, as I before said, it is merely at the beginning and end of pain that the liquor amnii has a disposition to escape. As the pains increase, a larger segment of the head becomes visible between the labia; during each pain it is thrust rapidly against the perinæum, which becomes greatly distended, and pushed out into a ball, and again slowly retires, not as the books say, gentlemen, because the cord is preternaturally short, or twisted round the child's neck or body; it is merely a result of the elasticity of the parts.

When more of the head has passed through it does *not* now recede, the perinæum is upon its greatest stretch, and is scarcely thicker than fine parchment, the next pain brings it, with the greatest circumference which it presents to the os externum, into the world; this is the moment of greatest suffering, and the head, as it passes through, is said to be in the *crowning, the caput coronatum* of the older authors.

An interval of comparative ease succeeds for a few seconds, and after two or more pains the shoulders and body of the child follow, and thus the fourth stage of labour is terminated. From their extreme violence, and from the great agitation into which the body of the patient is thrown, the pains during this stage have been called *dolores conquassantes*. The state of mind at this moment approaches nearly to a species of insanity, and shows itself in the most quiet disposition. Women who have been known as affectionate wives and tender mothers, have been guilty of words and actions the most outrageous and contrary to their natures, and at which they have afterwards been excessively shocked. Query—does the pressure of the abdominal viscera affect the circulation in the brain? This is a point of medical jurisprudence which does not appear to have been sufficiently noticed, and which is of great importance in cases of child murder.

At the birth of the child, a gush of liquor amnii, followed by a small quantity of blood, takes place. A delightful and perfect calm succeeds; in a few minutes pain of a slighter degree but of quite a different character comes on, and the after-birth or placenta soon follows. From the peculiar sensation which they communicate they are called *grinding pains*, it being apparently produced by the separation of the placenta from the uterus, or *dolores cruenti*, on account of the expulsion of the placenta being attended with more or less hæmorrhage. This discharge continues for several days after delivery, and is called *lochia*: at first it is called the *lochia rubra*, from the

mouths of the uterine veins being again uncovered by the expulsion of the membranes; thus permitting a portion of the colouring matter of the blood to escape, but as the uterus gradually contracts this discharge becomes colourless.

If there be twins, the second child enters the cavity of the pelvis in the third stage of labour; that is, the os uteri is fully dilated, and the parts prepared by the passage of the first child; the membranes form into a tumour and burst; and the whole is conducted precisely in the same manner as the birth of the first child.

There has been considerable discrepancy of opinion as to whether the placenta of twins are separate or not: some authors have affirmed that they are quite distinct, while others assert that they form but one mass. As far as I have had the opportunity of observing this point, I should say that when the placenta are sufficiently near each other, which is usually the case, the maternal portions, or that formed by the decidua, are continuous, whereas the fetal portions are distinct. Whether this be *always* the case is difficult to say: this has been noticed by Mauriceau and Portal, and, in some degree, by Levret. "If," says Mauriceau, "there be two children in the womb, they have commonly but one placenta, which has as many cords attached to it as there are children; nevertheless, they are separated from each other by their several membranes, in each of which the children are distinct with their liquores amnii.

So much, gentlemen, for the description of a natural labour. I might easily have rendered it more minute, but, by so doing, I doubt much if I should have rendered it more intelligible to you. Before concluding this afternoon's lecture, I must give you a few observations on the diagnosis of labour, and what are commonly called *false pains*. There is, perhaps, nothing of more importance to the accoucheur than to be able to distinguish with certainty when actual labour commences. Many women are subject, towards the end of gestation, to pains in the loins and bowels, very resembling those of labour: these have been termed *dolores spurii* or *false pains*, and are very apt to mislead the incautious practitioner. These pains vary considerably in their character; "they sometimes precede labour a few hours, sometimes several weeks, and generally harass most those addicted to the use of cordials*." The most frequent cause is flatulence, a spasmodic state of the bowels like colic, or irritation connected with costiveness or diarrhoea, especially after exposure to cold. If these pains become severe and constant, the abdominal muscles, or even the uterus itself, will frequently be observed to sympathise with them, and be affected with regular paroxysms of pain, during which they will undergo slight contractions and become

somewhat hard, as in actual labour pains. These appearances are so deceptive, that even women of considerable experience will suppose themselves on the very verge of labour. If the accoucheur examine the case more closely, and pay particular attention to the state of the os uteri (which, in fact, is the only means of ascertaining the real character of a labour-pain), he will find, that in spite of the pains and contractions to be felt externally actual labour has not yet commenced, the os uteri remaining closed and not participating in these changes. He will, therefore, be justified in considering that the contractions which he has felt in the fundus uteri are merely sympathetic with the colicky pains in the bowels, which, so far from showing the presence of actual labour, require to be alleviated by antispasmodics and such like remedies. In cases where flatulence seems to be the cause of these spurious pains, an ammoniated tonic, with a little tinct. opii or hyoscyami, will generally produce great relief. This requires, however, to be accompanied by some mild laxative, as the bowels are usually more or less loaded. A state of costiveness during pregnancy is best relieved by castor oil, confection of senna, or any such mild laxative, and the patient should be warned to pay strict attention to maintaining a due action in the intestinal canal. Where the pain is attended with diarrhoea which shows an inclination to assume the dysenteric form, blue pill combined with Dover's powder will have a beneficial effect. A little carbonate of soda or potash in cold water will relieve any acidity upon the stomach, which is frequently present in these cases, and serve to prevent the blue pill from griping: and if the tenesmus be at all troublesome, a starch enema with a small quantity of tinct. opii will be necessary. When, however, the uterus begins to sympathise with these various causes of irritation, and a hardness of the fundus is felt during the presence of the pains, a dose of liquor opii sedativus, or Dover's powder (as being preferable to common laudanum or crude opium), will prove a powerful antispasmodic, and cut short a state of considerable suffering, which might even have induced premature labour-pains. This is a circumstance most carefully to be avoided by the practitioner, because contractions of the uterus thus induced are very exhausting and inefficacious, and the labour is thereby frequently rendered exceedingly tedious and difficult. Not unfrequently the first contractions of the uterus, or *dolores praesagientes*, which, in a healthy state, produce little or nothing more than a sensation of equable pressure round the abdomen, in a rheumatic state of the uterine fibres are attended with very severe suffering, and produce a degree of irritation and exhaustion in the patient which cannot fail to do mischief.

These contractions of the uterus frequently come on as much as ten days, or even a fortnight, previous to the accession of actual la-

* Burns.

bour; and if, about this period, the patient has been exposed to the action of cold, or from any cause is liable to rheumatic attacks, the early part of her labour will be rendered unusually tedious and painful. These pains, like the other species of false pains above mentioned, have no effect upon the os uteri at first, but if their true character be not timely perceived, and the patient be treated as if in actual labour, a slight dilatation of the os uteri is produced, but, so far from continuing to advance, the progress of the dilatation soon ceases, and from keeping off the accession of real labour-pains, the patient becomes so exhausted, that, when actual labour does commence, she is too much weakened to make those exertions which nature requires of her. These pains being generally connected with a more or less accelerated state of the circulation, a venesection, followed by an opiate, seldom fails to give relief. Several hours of refreshing sleep are generally the result, and the patient wakes in a gentle equable perspiration, entirely free from pain.

—

CLINICAL REMARKS ON THE OPERATION FOR CATARACT, WHEN ADHESIONS OF THE LENS AND IRIS EXIST, AND ALSO ON THE TREATMENT OF CONSECUTIVE HYPOPION.

BY CARRON DU VILLARDS, D.M.P.

—

WHEN, before the operation of cataract is performed, the existence of one or more adhesions of the iris have been ascertained, very great precautions are necessary, for the operation becomes very difficult, so difficult indeed, that Richter regards it as very hazardous. I do not agree with him on this point, for provided that on the outer side, the place of election for the introduction of Scarpa's needle, a small portion of the iris be free, the operation may be successfully performed, by attending to the following rules.

1st. It is necessary to obtain the greatest dilatation possible of the pupil by means of the extract of belladonna, in order that the operator may be able to follow the movements of the needle with exactness and facility.

2ndly. Introduce the instrument as in the ordinary proceeding for depression, and carry it across the centre of the pupil, the point of the hook being turned downwards. Thence, if the adhesion be on the side of the great angle, the instrument must be passed on until it reach the band uniting the iris and the capsule. At this point the handle of the needle must be lowered, and the point raised, which is then to be carried gently on the adhesion, this latter thus coming in contact with the cutting point of the instrument. A few gentle movements backwards and forwards

with the hook will be sufficient to destroy the anormal bands which confine the iris.

This manœuvre, which is more easily performed than described, is almost always successful. It is to be repeated as often as there are bands to be destroyed; their destruction may be readily ascertained by the different forms the pupil assumes.

The advantages of this proceeding will be at once felt when it is stated, that Scarpa considered that whenever there were numerous adhesions between the iris and the crystalline lens or its annexes, depression ought not to be attempted. As soon as the lens has been freed from these anormal bands, it must be depressed according to the process of the Pavian professor.

There are, however, some glutinous lenses which can neither be depressed, nor reduced to pieces sufficiently small to be passed into the anterior chamber. In such a case, the crystalline must be broken into as many pieces as possible, and left to dissolve *in situ*; this recommendation was given in the year 1622 by Bannister, and published in 1683 by Barbette, in these words:—

“*Licet cataracta non satis intra pupillæ regionem sit depressa, dummodo in particulis sit divisa perfecta visio intra sex aut octo septimanas sc̄pissimæ redit, licet tota operatio absque nullo fructu peracta videatur: quod aliquoties experientia edoctus loquar.*”

CASE I.—*Adhesion of the Lens to the Iris; the former of a glutinous consistence; combination of the proceedings of Drs. du Villards and Barbette.*—M. Bauvais, seventy-one years old, an employé of the Countess of Osmond, was sent to M. du Villards by Dr. Chavernac.

This patient had had cataracts in both eyes for several years. The left had been operated on two years previously by extraction. The operation could not be completed, on account of numerous adhesions of the iris to the lens, and so many formed after the operation, that the iris and the lens appeared to be one substance.

Extraction of the cataract in the right eye appeared to be impracticable, and the operation of depression would evidently prove very difficult, on account of three very appreciable adhesions, which rendered the iris very irregular. The operation was performed in the presence of Drs. Chavernac, Therrien, and Brauzeau.

The first part of the operation was performed with the precautions already indicated, but scarcely was the needle directed to the performance of the second, than the crystalline lens broke into several pieces, without, however, any evident separation, and so that it was impossible to displace any portion with the needle. It was, therefore, broken up, and left for absorption. A few weeks sufficed to remove it entirely, and now the patient can see very well.

I had an analogous case in Madame Bertrand, residing in the Rue Basse du Rempart, in whom the phenomena of absorption were preceded by attacks of very painful intermittent neuralgia of the supra-orbital nerve.

Sometimes, after the operation for the extraction of a cataract, a purulent collection forms in the anterior chamber, which, under certain circumstances, makes itself a passage through the cicatrix, which it ruptures and deforms, and frequently causes a loss of vision; it were better, in such a case, that the surgeon should himself give exit to the retained pus; he may do it very readily by raising a small portion of the semi-adhering flap with the gold spatula of Forlenze. The pus escapes easily, the patient is relieved, and some time after a few drops of warm distilled water may be injected into the anterior chamber.

But when this purulent hypopion forms after the complete cicatrization of the cornea, a slight puncture must be made in this membrane, in order to evacuate the pus. This little operation ought to be practised with great precautions on the outside of the old incision, either with the lanceolate knife of Daviell, or the instrument of Jaeger for artificial pupil. It is the only measure that can be adopted to save the eye from the consequences of suppuration. The advantages of this proceeding were illustrated by the following case:—

CASE II.—*Double-dry siliquose cataract—Extraction performed on each Eye—Consecutive Hypopion—Puncture of the Cornea—Cure.*—Mr. Warms, an American, a native of Cincinnati, in the United States, was sent to me by M. Carneys, of Cadiz, on whose daughter I had operated for congenital cataract. This gentleman had two dry siliquose cataracts, the consequences of a violent blennorrhagic ophthalmia.

The operation was performed a few weeks after his arrival, in the presence of Messrs. Schmit, Bennati, and Brauzeau. Although I only operate on one eye at a time; in this case I was obliged to give up my usual custom, in compliance with the express wish of the patient. Although the extraction of the cataract of the left side was performed with some difficulty, in consequence of a band, which was destroyed with the kistótome; it was successfully accomplished.

Twelve days after, the patient having been very imprudent, a violent inflammation of the iris of the right eye took place; the intensity of the inflammatory symptoms was arrested, not without difficulty, by energetic measures, but a purulent exudation, in the anterior chamber, ensued, which caused considerable alarm, and required the eye to be punctured, which was done with success. The anterior chamber was twice injected with warm water, and the patient got perfectly well.

ABSTRACT OF AN ESSAY ON THE USE OF SEDATIVES IN MANIA MELANCHOLICA, ETC., ETC.

BY J. HORNE, ESQ., M.R.C.S.

Read before the Royal Medical and Chirurgical Society, Jan. 13th, 1835.

MR. PRESIDENT,—After this subject has been so ably introduced to the Society by Dr. Seymour, I feel that so young a member of the profession as myself may be considered presumptuous in renewing it. A consciousness of the immense benefit resulting from the plan of treatment, proposed by Dr. Seymour, is my apology, and I trust I have some claims to speak of its merits, having adopted it in preference to all others since 1830, and since which period a very considerable number of cases have fallen under my observation. The form of sedative, selected by the Doctor, is the pure acetate of morphia; I have chosen one which contains a very large proportion of the acetate of morphia in solution, and which I propose calling the *acetum opii sedativum*, as it will be found to be the same as, or at least very similar to, Mr. Battley's *liquor opii sedativus*, a remedy too well known to require description, except in regard to its mode of preparation, which the proprietor, in spite of the honour of ranking as a scientific chemist, has hitherto kept a profound secret.

[The substance of the observations, which follow has been already given in a preceding number, in a communication from Mr. Horne, headed "*Acetum Opii Sedativum*." These, therefore, we omit.]

Medical men are frequently consulted in cases of mania melancholica, arising from grief, vexation, or disappointment in love, and the dearer the object the deeper is the impression, the more difficult is it to be overcome. Mania not unfrequently sets in after females have undergone considerable fatigue, or kept late hours at balls, or have suffered from cold and fatigue combined, during menstruation. During this predisposing condition of the system fever ensues, and rapidly increases; the brain becomes affected, the secretions are arrested, hour after hour passes away without any rest. The mind, which at first only wandered, is now entirely lost. At this stage of the complaint the ceremony of taking leave of their friends, of dying, and of being buried is performed over and over again, or the constant fear of being murdered, or placed in solitary confinement in a madhouse constantly haunts them. All past actions appear to have been one continued scene of wickedness, from the commission of which it will be utterly impossible to escape everlasting punishment, or to make atonement.

The high degree of nervous irritation, producing these maniacal symptoms, has been combated by the profession with narcotic remedies; but, upon the whole, our medical

110. *Abstract of an Essay on Sedatives in Mania Melancholica, &c.*

writers consider that little reliance can be placed upon them. Experience, sanctioned by so great an authority as Dr. Seymour, will not allow me to attribute this want of success to the narcotic, but rather to the manner in which it is prescribed, due attention not being paid to these agents possessing two distinct properties, like the preparations of digitalis, that is to say, first stimulant then sedative, so that unless the dose of the latter be sufficiently large to counteract, or overcome the former property, that only will come into action, and this class of remedies would of course increase rather than mitigate the nervous irritability under which the system labours.

CASE I.—In the early part of February, 1831, I was requested to visit a lady, aged 18 years, labouring under this affection in its severest form. She had a wild and suspicious look, her eyes almost starting out of their sockets; she complained of the slightest noise; there was also pain in the head, with very dilated pupils, and indistinct vision; the tongue dry and coated; lips black; skin parched; pulse 135, small and weak, and respiration hurried. Insomnolency was a prominent symptom. She had been confined to her bed for ten days, and had taken a great dislike to all her attendants, deplored her unhappy condition, and dreaded the punishment that would be inflicted for her past supposed sins. Her friends were all in the greatest state of despondency, having given up all hope of recovery; two eminent physicians, who had been previously consulted, not having formed a favourable prognosis. I abstracted eight ounces of blood from the arm, and gave immediately thirty minims of the acetum opii sedativum, applied cold to the head, and supported the system by weak broths. The blood drawn exhibited slight inflammatory traces; the acetum opii sedativum was repeated throughout the first, second, and third days, at intervals of every three, four, and six hours, with well-marked benefit, and the pulse was kept down by digitalis. Three days and two nights passed by before sound quiet sleep could be obtained, and for the space of nearly two months the opiate was repeated at bed time, and also during the day, whenever the wandering, or melancholic mood, was on the increase, in varying doses from ten to twenty minims. The lady is now perfectly recovered.

A few weeks after a second case, presenting precisely the same symptoms, excepting the condition of the circulation, which was more excited, owing to this patient being more robust in constitution and habit than the former. Here the sedative proved most beneficial. At the commencement digitalis, with powerful diuretics, were employed to reduce the system, aided by occasional purgatives.

In chronic cases the same satisfactory results may be depended upon from the sedative plan of treatment; and, in further proofs of its efficacy, I may add the case of an elderly lady,

nearly 50 years of age, who became melancholic from reading religious tracts. I was consulted; and though well aware of the difficulty of successfully combating this form of melancholia, when arising from religious fanaticism, more especially as she had poverty to contend with, and but few friends to assist her, I considered it would prove a most favourable case for testing the efficacy of the treatment. Neither trouble nor expense on my part was spared, and my efforts were crowned with success, for my patient completely recovered, and in time became capable of following her religious inclinations with perfect safety. The dose of the sedative was twenty minims night and morning, gradually reduced to ten. The cure of this case stamped the efficacy of the treatment most completely on my own mind.

Other cases might be narrated, but as I am fearful of trespassing too much on the valuable time of the Society, I shall only relate one, belonging to the class of puerperal mania, which occurred in July and August, 1834.

I was requested to attend a poor girl, about sixteen years and a half old, whom I found in strong labour-pains. Parturition took place without much difficulty, and the child was strong and healthy. Up to the fourth day the patient was doing well; at 11 p.m. of the same day I was sent for by her friends, who were respectable, who reported that their daughter, towards the evening, began to talk excessively, and very strangely, quickly wandering from one subject to another; had attempted several times to get out of bed, but on being prevented at first quietly lay down by degrees, but she never ceased talking, and reasoning had no effect on her. On my arrival, I found two persons were required to keep her in bed; her exclamations were dreadful, and the manner in which she described the despised and degraded condition to which she had become reduced, and the helpless state of her child, will not be readily forgotten by me. The excitement had quickly developed high febrile symptoms; the pulse was 140 (rather more than less); the skin and fauces dry and parched; the head and the surface of the whole body were hot; the breasts distended with milk; the bowels had been relieved in the early part of the day.

This sudden change, I ascertained, had arisen from her parents' having inadvertently declared their incapability of keeping her and her child, and the only comfort they held out was the workhouse or starvation. I directed a wineglassful, to be given every two hours, of a mixture containing half an ounce of laudanum and ten ounces of water; the breasts to be drawn; lemonade drink during the night.

2nd. Symptoms increased; no sleep; the laudanum to be continued.

3rd. Worse; pulse sinking; bowels much relaxed.

Capiat tinct. opii ʒj. statim, et cochlearia larga duo 4tā quaquā horā misturæ sequentis.

R. Tinct. opii ʒij., aquæ ʒvi.—fiat mist.

4th. More composed; has enjoyed some sound sleep; to be supported by nourishing broths and milk; the opiate to be continued.

6th. Melancholia; expresses an ardent wish to die: pulse 70 and small; bowels confined.

Capiat pulv. jalapæ c. ʒij. statim.

Habeat mist. opii ut antea.

8th. Better; sleeps more composedly.

10th. Rapidly improving.—Continue the opiate.

13th. Convalescent; regained strength slowly, but her health has continued good up to the present time. The lochia were encouraged by warm fomentations, and were consequently unchecked; the milk returned in part as the mania decreased. In this case laudanum was given, because it contains spirit; considering it would prove beneficial rather than injurious on that account, on the ground that this class of patients are accustomed to spirituous stimuli, and its total deprivation not unfrequently retards the cure very considerably.

When insanity first develops itself in young persons, it is almost invariably accompanied, as in case the first, with well-marked symptoms of cerebral inflammation, and not unfrequently no inconsiderable tact will be required to arrive at a correct diagnosis. However, by attentively ascertaining the previous state and habits of the patient, and, if possible, the propensities, the true diagnosis may be formed, which it is of the greatest consequence to establish as early as possible.

Dr. Seymour, in his valuable paper, proposed to trust almost entirely to the sedative plan. My experience, small as it may be, compared to that of Dr. S., and with all due deference to the exalted rank he holds in the profession, enables me, with perfect confidence as to the result, to make it my sheet-anchor; but it also justifies me in adding, that there are two conditions of the circulation, a previous attention to which gives the narcotics an advantage and a power over melancholic insanity and puerperal mania, that no other class of remedies possesses. The first condition of the circulation to which I allude, is where we find, as in case the first, the action of the heart excessively quick, but the pulse weak, and in proportion to the time the circulation has continued unchecked, the greater is the weakness to which the patient is apparently reduced; the circulation, to use a common but appropriate simile, has the upper hand; by bleeding we relieve, consequently diminish the exhaustion, for the pulse falls, but becomes fuller, softer, and more dilated, the most satisfactory proof that the oppression has been in part removed. The second condition of the circulation alluded to is that

where the whole vascular system, from repeated indulgences and various excesses, too common and distressing to describe, especially when young, has reached its maximum of distension or dilatation. Under these circumstances, the necessity of reducing the powers of the system must be too evident to require demonstration.

Reviews.

Observations on the Causes and Treatment of Ulcerous Diseases of the Leg. By J. C. SPENDER, M.R.C.S. Pp. 210. Longman. 1835.

THE author, in writing the preface to this work, appears to have had two objects in view, one to dissuade the public from thinking him *egotistical*, the other to demonstrate that his work is not altogether devoid of novelty. How far he has succeeded our further analysis must endeavour to show.

In the commencement of the first chapter the author attempts to prove, that ulcerous affections of the lower extremities are not by any means referable to their dependent position, or remoteness from the centre of the circulation. The first thing, after exploding one theory, is to frame another, not always a better; and this he sets about in good earnest, but with bad success. He believes the cause of the evil is to be found first in the fact, that the inferior extremities are more exposed to the effect of external violence, as ulcers occur more frequently in men than in women, and among those who are employed in laborious and mechanical occupations; and, secondly, "in a positive and palpable unhealthiness of the outer structures of the leg, consisting of a varicose state of the superficial veins, either alone or combined with adventitious deposits, which are most generally the products of such varicose state." In attempting to prove the latter position he quite contradicts himself; for, after having spoken of the formation of the varicose valves, in preventing the retrogression of the blood, and endowed the veins themselves with a capacity of dilating, or diminishing, their calibre, according as a greater or less quantity of blood has to pass through them;—he says, "Now, from these two circumstances combined, viz. that the blood has to rise contrary to its gravity, and that the veins are endowed with a capacity for dilating themselves," &c. If he considers the circumstance of the blood *having to rise contrary to gravity* as a cause of the varicose condition, and thus of the disease of the legs, he must refer it primarily to their "dependent position." But he commenced by denying that the dependent position had any influence, whereas he has himself proved that it has a very great one, viz. in obliging the blood to proceed "contrary to gravity," and thus he has proved himself to have denied a fact which he subsequently admits. He

appears to have been aware of this inconsistency, and has added a note, but we must confess that, in our opinion, he has only made "confusion worse confounded."

In the classification which he offers of ulcers, he disapproves of the practice of arranging them according to their external appearance, and distributes them under two general heads, viz, those which possess and those which want the varicose affection. We fear that this is generalising a little too far; but on this point we will not quarrel with him.

In the remarks he offers on the treatment of ulcers, he appears to view the practice of others in a most contemptible light. According to his statements ulcers, of whatever description they may be, are indiscriminately "wrapped up in a poultice."

We give the following extract as an illustration of his views of the practice of his contemporaries:—Page 90. "Nothing has ever astonished me more than to see the frequency with which patients, who apply to me with bad legs, have the limb *wrapped up in a poultice*. Cases of the most opposite description, young and old, recent and long standing, irritable and indolent, exuberant and callous, are all subject to this indiscriminate remedy. I have been in the habit of recording what kind of application is found on every sore when I first examine it; and I see the result is, that out of a hundred cases sixty-one, considerably more than one-half, were covered with the *poultice*, whilst some of the others, though not using it at that particular time, had employed it at a former period. I have seen many legs in which this treatment had been pursued for years; a pretty convincing proof, by the way, that such a proceeding is not calculated to do any good."

A few pages further we are favoured with the following comment upon the fastidiousness of the medical attendant. "It is really difficult to assign any other cause for the frequent and indiscriminate use of such a remedy, than the disinclination to do anything which will soil the fingers or offend the nose. We can order a poultice, and even prescribe a fomentation, or lotion, and yet stand at a very agreeable distance,—shifting off on other hands the local treatment of the disease, instead of executing it by our own. It is, however, very clear, that if the performance of what ought to be done strikes us with disgust, though it may be allowable to dislike it, yet if the aversion prevents us from doing our duty, we are inexcusable for pretending to undertake the management of the case at all."

We leave it for our readers to decide whether or not this is the practice in our hospitals, or amongst liberally educated medical men. With every disposition to do justice to the work, we must say, that the author appears to have overstrained his mode of treatment. We think his practice is very good and no doubt very successful, but yet we do not see that it lays claim to any great originality, or that it has

any material difference from that taught in the various schools, and practised in the different hospitals in the metropolis.

The work before us is not likely, we apprehend, to be read much by the scientific portion of the profession, inasmuch as the opinions it professes to promulgate are pretty well known to them already. We fear the perusal of it will, in a great measure, be confined to those who have hitherto been in the habit of *poulticing* on all occasions, and who would probably have continued so to do unless reminded of the "evil of their ways" by the timely publication of Mr. Spender's work.

The London Anatomist;—Anatomical Plates Parts I. to IV.—or, *a System of Anatomy, Physiology, and Surgery combined.* By G. D. DERMOTT, Lecturer on Anatomy, &c. No. 1. pp. 93. Oct.

Had we space for a long review, we might probably endeavour to estimate the character of the author as a teacher of anatomy, as well as a political and a theological controversialist, but as a discussion of the two latter topics would neither enhance the reputation of Mr. Dermott in his profession nor interest the readers of this Journal, we shall waive them, and therefore refer only to his anatomical productions before us.

The anatomical plates naturally come first, from their priority of publication. The present plate is the *fourth*; it presents a very clear view of the *inferior angles* of the neck, with the muscles, vessels, and nerves; the vessels and nerves of the axillæ, fore-arm, and hand, the subcutaneous veins at the head of the elbow, with their relations to the cutaneous nerves, and of the median basilic vein to the brachial artery, are accurately depicted and superbly finished.

The *first plate* presents the structures of the head and neck in a similar manner, and the *second and third plates*, those of the inferior extremity. The letter-press is on distinct sheets.

When we say that they are exceedingly good plates, we offer no small meed of praise; but in justice we must add, they excel all that have been "got up" in this country; in addition the price is very moderate.

The "London Anatomist" will remind an old student of the "London Dissector," but we must inform him that they are very opposite works. The latter contains a concise description of the different structures of the body displayed by dissection, the former comprises a full view of anatomy, descriptive, general, and surgical, with physiology and morbid anatomy.

With descriptive and surgical anatomy Mr. Dermott is well acquainted; he could not have taught the subject so long without being so. For those who have not heard Mr. D.'s descriptions, we shall extract a small portion, and without comment or selection. His physiology we do not admire, for he is warped by

some peculiar and intangible notions; he will enter too deeply into the labyrinth of nature; he is fond of exploring in the dark recesses, and thus often loses himself in perplexities; he looks more deeply than his senses can penetrate and behold.

How great may be Mr. Dermott's experience in morbid anatomy and surgery we are not aware, nor is it our business perhaps to inquire, but we shrewdly suspect it is not vast.

This is the first number: to how many the work will extend does not appear. It contains—what do you think, reader?—in the Introduction, "Observations on Reviewers," in which he states, that if dealt with unfairly, he claims a reply—on the concours, on medical politics, &c., &c. This we regret to see; it is greatly misplaced.

The first chapter is on the "Physiology and Development of Bone, with its Diseases." At page 17 we observe an error:—"On the outer surface of bones," he says, "is a thin membrane continued uninterruptedly over the whole skeleton. It is rather tough, whitish, and is called, from its situation, the *periosteum*. It is a cellular membrane of a certain degree of condensation, and therefore it is of the serous kind."

We thought that the periosteum was alike in structure to the dura mater, the ligaments, and fasciæ; that it was a *bonâ fide* fibrous structure, and not a serous: this is the opinion of the Continental and best British authors. They are all cellular tissue woven into layers or cords, essentially the same in structure and properties. The *serous* is an elastic, transparent, shining structure, very unlike *fibrous*. In the chapter on "General Anatomy," which is likely to appear in the next number, we would suggest the author to remember this little point.

Chapter the Second is an "Introduction to the Bones of the Cranium." Then succeeds the "Descriptive Anatomy of the Bones proper and common to the Cranium."

"The *general uses* of the occipital bone are—to form, and close in, the posterior and inferior part of the cranium; to support and protect the cerebellum and the back of the cerebrum; to transmit the spinal marrow; to give insertion to the more powerful muscles moving the head, and protection to the conflux of the larger sinuses of the dura mater.

"It is absolutely necessary to be familiar with the position of the tubercle at the back of the head, and to be able to calculate upon the relative distance of the sutures from that point, as well as of the depressions upon the inner surface of the bone which give lodgment to the projections of the brain, and the sinuses of the dura mater. It would be extremely difficult to trephine upon the internal crucial spine; observe that the bifurcation of the superior longitudinal sinus, the centre of the internal crucial spine, is opposite the tubercle: that the transverse limb of the latter spine,

and the lateral sinuses, are opposite to the superior transverse ridge. At these parts the bone is consequently very thick; this is evidently a provision of nature to protect the larger veins of the head, and is in correspondence with the manner in which the large vessels are protected, in the muscular parts and the limbs, by the bones.

"The occipital bone at *birth* consists of four portions, which are formed from four centres of ossification, and held in connection by intermediate membrane. One ossification comprehends the tuberos process and the larger superior part, or body of the bone; in the lower parts or sides of this fissure are often seen. Two others are at the condyloid processes, and form considerable portions of the foramen magnum, as well as rather more than the posterior halves of the foramen condyloidea antica. A fourth ossification constitutes the basilar process. Early in utero-gestation, the superior portion instead of being formed from one centre of ossification, is really composed of four, which, rapidly coalescing, constitute the tuberos processes, whence the fibres subsequently spring as from a common centre of radiation.

"Additional centres of ossification are frequently generated towards the edge of the bone, which either become blended, as they extend, with those that are regularly formed, or are left insulated by a serrated suture, and then termed *Ossa Wormii* vel *Triquetra*; they are generally, however, not triangular.

"*Connections*.—The occipital bone is connected, *superiorly* (the lateral and superior edges), to the posterior edges of the two parietal bones, and to the *Ossa Wormii*, should they exist, by the *sagittal suture*: *more laterally and inferiorly* (the lateral and inferior edges), to the mastoid and petrous portions of the two temporal bones, by the *additamenta suturæ lambdoïdalis*. The *anterior part of the basilar process* is connected, previous to maturity, to the basilar process of the sphenoid bone, by an intermediate cartilage or *synchondrosis*; and, subsequently to the period of maturity, by a coalescence of osseous substance, that is, a natural ankylosis or *synostosis*; and, lastly, the *condyloid processes* are articulated, by *ginglymus*, to the superior oblique processes of the atlas."

With this extract we close the review, wishing Mr. Dermott every success in the sale of his work, which it eminently deserves, recommending him at the same time to avoid prolixity in his descriptions, and particularly to avoid long names.

Reports of Societies.

MEDICO-BOTANICAL SOCIETY.

February 10th, 1835.

CHARLES JOHNSON, Esq., Lecturer on Botany at Guy's Hospital, was elected a Fellow of the Society.

Mr. Iliff, of Newington, presented a drawing of the rock on which the fungus *Melitenis* grows, and some of the tincture made from the fungus. He also presented some specimens of the galangal and zedoary roots.

Some specimens of the kinogambier were announced as presents from Mr. Reece, and there was also on the table a specimen of the official tincture of kino, in its proper condition, and of some which had assumed a completely gelatinous form.

Dr. Sigmond, the senior secretary, made some remarks relative to the kino, galangal, and zedoary. He observed that a different source was assigned to the kino by the framers of the three Pharmacopœias,—the Dublin Pharmacopœia considering it to be a production of the *butea frondosa*, the Edinburgh of the *eucalyptus resinifera*, the London of the *pterocarpus erinacea*. Its origin appears to be involved in great doubt; and, as it is a matter of considerable interest, it had engaged the attention of the two great botanists of India, Drs. Roxburgh and Ainslie, who, however, had left the matter undecided. It should seem that the substance now in the market is the product of the *nauclea gambier*, from India, while others again consider it to be the inspissated juice of the brown gum-tree of Botany Bay. While examining the tincture prepared by one of the London chemists, the Doctor was surprised at perceiving a peculiar appearance one specimen presented, and which he was informed was not unusual, and, when it happened, the tincture was considered *effete*.

The specimens which were on the table of the good and bad tinctures were then passed round. The good had a peculiar astringency and a strong alcoholic taste; it was perfectly liquid and transparent. The bad preparation had a similar colour, but was completely gelatinous, had lost its astringent taste, and retained only partially its alcoholic flavour. It was stated by the chemist who furnished these specimens, that this gelatinous condition was considered to be owing to the cold weather, the tincture having been made immediately previous to such a change in the weather; but this, it was remarked, could not be the only cause, as it would sometimes occur when the atmosphere was warm. The kind used in preparing both specimens was taken from the same parcel, and proof spirit was in each instance employed.

The Professor of Chemistry was called upon to explain this peculiar condition of the tincture, but he stated that it was impossible to do

so without making an analysis, as it would be scarcely worth while in the present instance, as the source of the kino in the market was unknown; it would be, in fact, operating on a substance of which no one knew anything.

[We feel inclined to suggest to the Professor of Chemistry that some advantage might be derived from an analysis in the present instance, inasmuch as, although the knowledge of the composition of the kino would be of little avail while we remained unacquainted with the plant which produced it, yet by analysing the good and bad tinctures, and ascertaining their proximate principles and their ultimate elements, the cause of this peculiar change might be discovered.]

Dr. Sigmond then proceeded to make some remarks on the specimens of the galangal root which had been presented to the Society. He states that there were two species, the greater and the less, both of which were employed in India in cases of dyspepsia and some other stomachic complaints, but the lesser galangal was more highly prized than the other variety. It is considered to be warmer, and more fragrant: it is much used in India, China, Sumatra, and Japan. In the three former countries it is indigenous, and cultivated in the latter. The lesser variety is brown externally and reddish internally, the larger brown externally but of a dirty-white colour internally; the larger may also be distinguished from the other by its having rings on its external surface about a quarter of an inch distant from each other. The root is tuberoso, has an aromatic odour, and a pungent taste, like pepper and ginger combined. It is employed in the form of infusion. M. Robert procured starch from the lesser galangal.

Of the zedoary, there are three distinct plants, of the class and order monandria, monogynia, namely—the zedoaria *Kœmferia*, the zedoaria turmeric, and the zedoaria *zerumbet*. M. Robert has discovered starch in all these. He said it was considered at Malta to be an excellent astringent, but he himself did not place much confidence in it. It is employed either in the form of tincture or electuary.

Dr. Sigmond afterwards read a part of an essay, written by a German physician to compete for the gold medal of the Society. The question for the solution of which the medal was offered was,—What vegetable substance has been found most efficacious in the treatment of cholera? The essayist appears to depend on the *spiritus terebinthinæ*, combined with the liquor Hoffmanni, and the tinct. opii. In the paper a great deal of skill and acumen was displayed. The author alluded to the atmospheric changes for some time previous to the invasion of the epidemic; he also describes the class of diseases prevailing endemically or epidemically before the appearance of the cholera, and seemed to draw from these the conclusion that cholera was an affection of the spinal cord or nerves. In one part a

parallel was drawn between the symptoms of this disease and those exhibited by well-recognised spinal complaints, and the semeiology appeared to tally tolerably well, although it was not quite accurate.

[It is rather a curious fact that more works have been written on spinal diseases within the last few years than at any other antecedent period.]

It was announced that at the next meeting Mr. Everitt, the Professor of Chemistry, would make some observations on the preparation of atrophine, and that Mr. Hanham would detail his plan of preparing plants for herbaria.

LONDON MEDICAL SOCIETY.

Monday, February 16th, 1835.

W. KINGDON, Esq., in the Chair.

Hermaphrodites.

WE should not notice the meeting of this Society on last Monday, if the medical discussion had been the only object of interest. As an adjourned debate, on a case narrated partially the previous week, and continued but not completed on the 16th, it would not afford sufficient data to interest our readers, or consequently to warrant our inserting any notice of the proceedings.

But in the course of the evening, Mr. Stephens produced two young pigs, one of which he considered to be a specimen of hermaphroditism. On examination, the female parts of generation appeared to be well developed, and immediately in front of these there were two tumours contained in a cutaneous envelope, but not separated from each other by a raphe. The integuments enclosing these projections were not in any way wrinkled, and appeared to be simply a continuation of the skin of the abdomen. The tumours were considerably larger than the testes of the pig at the age of that under examination; they did not present any glandular feel, but gave rather a sensation as if a thickish membrane was being pressed between the fingers; considerable pressure on them did not cause any great indication of pain, but gave a jingling noise, as if something were receding from beneath the fingers. The tumours could be returned into the abdomen, and the finger readily followed them through the abdominal rings. Their cuticular covering then appeared to be decidedly nothing more than a lax portion of the integuments of the abdomen. By causing the pig to squeak and struggle, the tumours were again protruded. There was not any penis, nor even the rudiments of one. From these data, the conclusion seemed to be universal that the animal was a female, labouring under double hernia, but in no respect a hermaphrodite.

DR. CAMMACK ON THE USE OF SEDATIVES IN PUERPERAL CONVULSIONS.

To the Editors of the London Medical and Surgical Journal.

GENTLEMEN,—The following case may perhaps interest some of your readers, as showing the advantage that may occasionally be derived, even in puerperal convulsion, from a full dose of an opiate, after due attention has been paid to emptying the vessels, &c. Every case, however, has some peculiarity of its own; and this having occurred *after*, may perhaps be considered as differing from convulsion *previous* to, delivery.

Mrs. Walker, a delicate woman, the wife of a labourer, aged 23, was delivered of her first child by Mr. A. Foote, on Sunday night, the 28th Sept. last, at half past eleven, after an easy and natural labour of ten hours' duration. Nothing particular occurred during the labour, except that during the last few pains, which were rather severe, her screams were violent, finishing with an agitated giggle. The placenta came away about ten minutes after the birth of the child, and Mr. Foote remained in the house nearly an hour afterwards, leaving her in a very comfortable state.

Soon after one o'clock he was sent for in great haste, with intelligence that she had fainted. On arriving she was quite composed, but with her pulse quick and feeble, her countenance pale, and every symptom indicative of exhaustion. He made an examination, but found there was no flooding, as he had apprehended, to possibly cause such symptoms. The uterus, however, being flaccid, he removed several coagula; and applying friction externally, and a shawl moderately tight round the hips, succeeded in producing full contraction of that organ. Mr. Foote sat by the bedside for some time to ascertain if there was anything more to account for the symptoms described to him; as, on cross examining the different parties who were with her, he could get nothing further from them than that she "had tossed up her arms suddenly and became like a ghost." At half past three, when about leaving the house, he was hastily summoned again to the chamber, and found her in a state of strong puerperal convulsion, which lasted several minutes. Her friends objected to his taking away blood, which had been immediately proposed. He sent for me, and blood was then taken from the arm to the amount of eighteen ounces, so as to produce a sensible effect upon the pulse, reducing it from 120 to 86.

The bowels were copiously evacuated in the middle of the day by means of an enema; and at 4 P.M. my brother, Mr. Robert Cammack, introduced the catheter and drew off two pints of thick turbid urine.

8 P.M.—The convulsive fits continue to come on at intervals of an hour, followed by increased coma; pulse 120 and harder; the face is flushed, and she is complaining of her head. The lancet was again used; taking eight ozs. of blood produced a very decided effect on the pulse and system, so as not to allow of more being abstracted. Sinapisms were applied to the inside of the legs, and a blister to the nape of the neck.

30th. 8 A.M.—The convulsive fits still continue to return with unabated violence, followed by coma; the pupils are fully sensible to light as they had been yesterday, though the introduction of light into the room does not seem to make any impression upon her. The head continues hot, and she complains of occasional darting pains in the forehead. The tongue is coated and dry; pulse 88 and rather oppressed; there is great restlessness. A vein was again opened and eight ounces of blood abstracted. The effect it had on the pulse was very decided, rendering it extremely soft and weak. The blood does not exhibit any particular inflammatory appearance.

1 P.M. The convulsions continue to return in the same way. She is very restless in the intervals, and now perfectly insensible. She has had a copious watery evacuation. The pulse is 100, small and feeble; head not so hot; face flushed; tongue coated with a light brown fur.

R. Ext. hyoscyami,

Camphoræ, āā. gr. iv.

Aq. ℥ x.—M. fiat haust. s. s.

After taking the draught she became less agitated for a short time, but the convulsive fits recurred as usual.

3 P.M.—The convulsions, especially of the muscles of the face, have become more frequent and protracted. During the intervals she is excessively restless, tossing about in every direction. The pulse is 120 and feeble; the breathing is become stertorous; the skin hot; the pupils readily contract. There is no lochia or secretion of milk; the bowels are freely open. Further depletion appeared altogether inadmissible; the convulsed and agitated state of the system seemed to be rapidly wearing out life; and the only plan to be pursued at this moment appeared to be, if possible, to check it.

Aquæ ℥ x.—M. ft. haust statim sumend.

Cont. hydr. submur.

The tincture to be repeated in two hours if not more tranquil.

8 P.M.—She has had a continuance of coma since four o'clock; and, except when the fits have come on, which have not been so violent, has remained quiet, but with an almost incessant convulsive twitching of the muscles of the face. The countenance flushed; the skin hot and dry; the tongue furred; the pupils acutely sensible to light on bringing a candle near the eyes; the stertorous breathing is greater; the pulse 120 and harder. It was at first thought right to again use the lancet, but the pulse, on sitting by the side of the patient, was found to vary so much, at one time fuller and harder, and again softer and rather less frequent, varying from 100 to 120, that the application of twenty leeches to the head was preferred. The cold lotion and submuriate were continued, and forty minims of the tinct. opii ordered to be repeated if much restlessness returned.

Oct. 1st. 10 A.M.—There has been no fit since last night at eleven; the pulse is 90, soft and compressible; tongue furred. She is very restless; the convulsive motions of the face are chiefly confined to the muscles of the mouth; the pupils are still equally sensible to light; the bowels have not been relieved.

Cap. statim ol. ricini, ℥ ss.

No urine having been passed since yesterday, the catheter was again introduced, and Oss of dark fœtid urine removed.

Cap. tinct. opii, ℥ xxx. formâ haustûs.

In the middle of the day the pulse became 80, small and compressible. The oil not acting, an enema was exhibited. There was now some drawing up of the legs, which was partly attributable to a feeling of soreness from the sinapisms.

7 P.M.—Great irritation has come on in the intestinal canal, with frequent bloody and slimy evacuations. The convulsive motions of the face are diminished; the respiration is improved; the pulse 96, and more wiry; the head hot; the pupils equally sensible to light; the general restlessness not so great. Ten leeches were applied to the left temple, on which side the heat of the head was greatest;

they bled freely, and reduced the pulse to 86, rendering it much softer. Fomentations were ordered to the body.

Oct 3rd. 10 A. M.—After the exhibition of the enema amyli last evening a disposition to sleep came on, and the restlessness was much abated. The pulse is 96 and compressible; the pupils appear natural. She is sensible to passing impressions this morning for the first time since the early part of the morning of the 30th, though not collected; the tongue is furred; the feet are cold, which they have not been previously. She complains of pain in the abdomen, upon pressure, and in her head. The motions are more natural but frequent.

The feet were ordered to be wrapped in warm flannels, and bottles of hot water applied.

Appl. abdom. hirud. x.

To take the powders and mixture every six, instead of every four, hours.

Oct. 4th. 10 A. M.—She is more sensible this morning, but has no recollection of her delivery, or of any thing that had occurred a few days before it,—wishing “it was over,” and wondering “when it would be.” She has passed her urine freely, and had two natural motions.

5th. 10 A. M.—To-day, after passing a good night, she continues mending, with the tongue gradually becoming cleaner. The breasts are now painful with a plentiful secretion of milk, but there is no lochial discharge. From this time

she continued gradually to become more and more convalescent till her perfect recovery.

The result of the case was very satisfactory, inasmuch as the decided effect of the opiate, in quieting the convulsive action, was very evident, at a time when the danger appeared to be not only imminent, but so great as to render the chance of recovery almost more than hopeless.

Should you, on looking it over, think it worth insertion it is very much at your service.

I am, Gentlemen,

Your obedient servant,

THOS. CAMMACK, M. D.

Spalding, Feb. 10th, 1835.

OBSERVATIONS ON MR. BARNARD'S
COMMUNICATION OF “GONORRHŒA
FROM MENSTRUATION.”

To the Editors of the *London Medical and Surgical Journal*.

GENTLEMEN,—A correspondent, in No. 156 of your valuable Journal, gives a description of two well-marked cases of gonorrhœa, but his explanation of the origin of the disease seems to be contrary both to experience and to reason.

In the first place, I am not aware of any cases on record of gonorrhœa being attributed “to the irregularity of living, and great disturbance of the menstrual function, the fluid becoming vitiated in quality, and acting as a morbid poison.” As your correspondent states that similar cases have been “noticed before,” he certainly will very much oblige me by referring to them. Upon questioning, too, all practitioners on the subject, I ascertain that they have never heard of the disease having been contracted in this manner, neither have they seen any such cases during a long series of very extensive practice. Referring to a lecturer on Midwifery and the Diseases of Women and Children, a person of great experience, concerning the probability of the disease ever being produced in this way, I am still further confirmed in the opinion that nothing less than the distinct specific—gonorrhœal virus—can communicate the disease.

It would have been much more satisfactory, and have attached a greater apparent authenticity to the facts stated, had your correspondent given the reasons of his conviction that they did not proceed from direct application of gonorrhœal virus. He says “the foregoing cases, I am convinced, did not arise from a female labouring under gonorrhœa,” &c. &c. Now, in order to be *convinced* that neither party had been exposed to the poison, requires very strong evidence indeed. He has given two cases of gonorrhœa; and what can we infer from the above sentence, than that one female (“a female”) communicated the disease to both the males? If this were the fact

our suspicion as to the origin of the disease would be greatly verified, and I would say that the disease had its origin in the latter, from direct contact with gonorrhœal virus lodged within the vagina of the former, and which had not produced any effects upon the female, for we well know how particularly some persons are predisposed to the disease more than others; and we have frequently seen cases of gonorrhœa arising from connexion with females who have not been aware, at the time, of one single symptom of the disease existing within themselves, and who have not communicated the disease to others less predisposed to it. We can only account for these circumstances, then, *by the difference of predisposition existing in different persons, and the capability of gonorrhœal matter within the vagina communicating the disease, although it had not manifested any of its usual effects on the female.*

The above are the conclusions I should be inclined to adopt, did one female communicate the disease to both males; but to suppose that one person, in whom there might be varied interests for concealment of the disease, communicated the virus in these two cases, is incompatible with your correspondent's conviction, that she was not labouring under gonorrhœa. If there were *two females* concerned, as I suppose there were; if they are married, and sufficiently impressed with a sense of moral rectitude to prevent their exposure to a chance of contracting the disease—in fact, of unimpeachable character, I should, then, be doubtful with reference to the *gentlemen*. How often do we see men with gonorrhœa, who most solemnly declare having had connexion with no other persons than their wives! They feel very anxious about their condition, and inquire very innocently as to the nature of the disease, and how it could have possibly occurred; yet, on positively declaring to them the disease, and the impossibility of its having been contracted in any other way than by direct connexion with persons affected with it, we may often infer, from their undecided answers and manners, the true nature of the cause; for there is no MAN who, under these circumstances, would still persist in vindicating his own character to the reproach of that of his innocent partner. I merely mention this fact as a fair specimen of a great number of cases. It matters little to medical men whether the disease were contracted in this or that way, if a patient come to him labouring under gonorrhœa or syphilis; and they would as soon attribute the origin of the latter to the menstrual discharge "vitiated in quality," &c. &c., as of the former.

We have sometimes seen slight excoriation and irritation of the part produced by the leucorrhœal discharge, but not gonorrhœa, and I should be inclined to suppose that the discharge in leucorrhœa, scirrhus tumour, polypus, cauliflower excrescence, and confirmed cancer of the uterus, would be more

capable of producing gonorrhœa in the female, than any altered condition of the menstruous fluid, but I have never heard of any such occurrence.

In the second place, it is reasonable to conclude that were this disease able to have been communicated in this way, we should, ere now, have had an abundance of cases to have testified the menstrual fluid as a "morbific poison" enabled to produce gonorrhœa; if this was the case, gonorrhœa would be a frequent occurrence from any "disturbance of the menstrual function," from "bad habit of body," &c., and the virtuous husband's blissful prerogative of freedom from a disease more deservedly attached to the *débauché*, would, in a great many instances, be annihilated. This chain of argument might be carried to a great length, but as I have so far (and a great deal farther than I intended when I commenced), I must now conclude, by negating the former query of your correspondent; the latter was unnecessary; we know that gonorrhœa is communicable from person to person, and of course if a man have gonorrhœa, however it may have originated, he is capable of communicating it to a female. Then I would say, that a man, from having had connexion with a woman during the period of her menstruation, cannot afterwards, from that cause, be affected with gonorrhœa, and I am not aware of any cases on record likely at all to require an opposite conclusion.

I am, Gentlemen,

Your obedient servant.

VIEWS OF THE GOVERNMENT WITH
REGARD TO THE COLLEGE OF
PHYSICIANS.

In our last number we observed, that the Government contemplated to amend so far the code of laws of the College of Physicians, as to render the admission of Licentiates more easy, and to increase the number of Fellowships, making the latter open to all Licentiates without the necessity of a Collegiate degree. We then remarked, that the examination for the licence, to be effective, should be both theoretic and practical, no reference being made to the place of study, or the in-

terests of any particular school pandered to; all that should be required of the candidate being a satisfactory proof of his thorough capability for the profession.

One important portion of the good emanating from such a state of the law would be the facility with which those among general practitioners, who might wish to receive fees instead of sending in a bill of charges for medicines, &c., could obtain the degree and consequence required; for many, as the law stands at present, though desirous of obtaining the degree, and amply qualified, so far as knowledge is concerned, are unable to fulfil their wishes, owing to the innumerable obstacles, in the forms of bye-laws, flung in their way. The usual mode now adopted by an individual of the above description, is, to gallop down to Edinburgh, leaving his business here in probably uncertain hands, and while there to pursue a system, which, while it cannot improve his knowledge, drains deeply his finances. To be obliged to con over again what one is well acquainted with, is no pleasant task, and certainly ought not to be enforced, where the applicant is ready to undergo a searching and effective examination.

But then it may be questioned whether the present amount of examination be a sufficient test of capability, and with great justice, for assuredly the few questions now put, and answered in the brief space of an hour, cannot be considered a satisfactory scrutiny in so grave a subject. The examination, to be efficient, should not be that of a day, or even a week; the theoretic portion, indeed, might be despatched in one or two appearances of an hour's duration, and should of course precede the practical, which should be the *argumentum crucis*. This latter should be long and rigid, and might be commenced by requiring the candidate to

attend in one of our dispensaries, there to receive and treat a stipulated number of patients, and to describe both their cases and treatment in writing. The term of this trial might be extended as circumstances seemed to require from one week to a month; at the conclusion of which another examination should take place, the subject of which might be the cases just attended by the examinee. In this his motives for his treatment should be narrowly canvassed, and accurately explained. On his properly acquitting himself a final trial should be decreed. In this a certain number of difficult and complicated cases, selected in a hospital, should be placed under his care, and the management of them noted as before by competent judges. Perhaps a week of such discipline would be sufficient, when his concluding examination taking place, a clinic on each case should be required, and, if approved, the licence granted. Such a mode of proving the candidate's ability would be at once a shield of protection to the public against the fangs of ignorance, and a mark of excellence in the College; solid benefit would thence accrue to its members, and their credit for capacity, now more than apocryphal, become re-established.

That a more rigid enquiry into the qualifications of candidates, than that adopted at present, is called for, we believe none, excepting perchance an old Fellow of the reigning regime, can be hardy enough to deny. To talk is easy, to practise is difficult; verbal examinations without practical exemplifications are easily *gotten up*, and to render them public, as some have thought advisable, would not render them more effective,—for public examination upon scientific subjects, when the credit and often the fair prospects of the examined are involved in

the result, cannot be equally just as respects individuals; the weak nerved and timid, though well prepared, may easily be distracted, and rendered for the time confused, while those of the iron strings successfully repeat their task,—this view of the question would make it in some degree one of animal courage and not scientific acquirement.

In divinity, before a degree is granted, the scrutiny into the classical and theological attainments of the candidate is protracted, and in the first step of A. B. severe; a long term of preliminary study, under the most favourable auspices, is demanded. Here, as words are the means by which the Divine administers his function, a verbal examination is deemed sufficient; but in our art, the application of which consists of operations and of tangible forms in various combinations, it does not follow, that because the words, which express the manner of such operations, or the modifications and tendencies of various medicaments, are remembered and pronounced, the practical tact is possessed; but without that tact there is no utility. A man might with little labour read a lecture upon the structure of a watch, or other engine, who could not put in order any misadjusted part of it, or indeed discover where the error lay. A man might commit to memory the members and positions of any complex apparatus, and undergo an examination, proving him acquainted with the same; but dismember the machine, and placing its component pinions, levers, and wheels isolated before his eyes, require him to restore its integrity, and his confusion would quickly become manifest. It is so with our art, its value to society exists but in its practical application, to which theory is only the handmaid, and shall we longer, rejecting the substantial part and grasping

at the shadow, leave to empty sound that of which both the eye and the ear should alike judge; in a word, shall we make our examinations tests of practical ability, as they ought to be, or merely proofs of what a strong memory and a tolerable stock of assurance can do?

It may be objected by some who think it as fair to conceal ignorance as to display knowledge, that the plan now sketched will be too great an innovation on our established usages, and that we ought to have recourse to a practical investigation of the candidate's competence. To these we answer, it is the only mode in which a fair estimate of his ability can be arrived at, the only mode in which justice, so far as the College of Physicians is concerned, can be administered to the public, and the only one which can give our now lame and halting science that impetus it has so long wanted, and which will make it progress, *pari passu*, with the intelligence of those after all most benefited by its advancement—the people.

REMARKS ON THE METHOD OF PRESCRIBING.

THE state of the law in England respecting venders of drugs and chemicals, is so loose and ineffective, that any one so inclined may adopt the business, no other qualification being required than the pecuniary means; and, owing to this oversight in legislation, by far the majority of our chemists and druggists are destitute of any peculiar qualification for their trade, knowing, in many instances, little or nothing of the nature of the drugs they retail. We say the majority, for we would not, as some of our contemporaries have done, include all in one sweeping accusation of ignorance. Doubtless there are among them a few possessing education, experience, and a thorough know-

ledge of their business, and to such the dispensing of prescriptions may be trusted with safety; but as this only happens to a very select number indeed, it behoves the medical profession to be as explicit and careful as possible in the wording of their prescriptions, in order that they may be comprehensible to the small intellects of those who may have the compounding of them.

We have been led to make these observations from noticing, under our head of Foreign Medicine, last number, the precautions which the Prussian authorities take to prevent any mistake happening in the dispensing department. In their Pharmacopœia appears a table pointing out the largest dose of certain medicines which ought to be administered, and forbidding any increase of such dose, unless in cases where a properly qualified physician deems it advisable, and then requiring him to affix a note of admiration (!) to such increased quantity. This is a regulation which confers an immunity from consequences upon the dispenser, should he send the overdose, and fixes the physician and his note of (!) with them; on the other hand, should the chemist venture to infringe without this staff (!) of safety, he is liable to all the cudgelling which may ensue. It would be a curious and not uninteresting subject for investigation to examine into the doses from time to time administered at certain of our metropolitan hospitals, and confer on them, according to the above systems, their proper marks of distinction; for instance, some enormous doses we have heard of might vindicate to themselves at least a brace of these (!!) worthies, while a glorious *ne plus ultra* of (!!!) might marshal in those unheard-of increasing potations of poison which have been swallowed with impunity, *mirabile dictu*, by patients

endowed with more than the antidotic power of Mithridates. Surgery might also come in for a note or two, and a long cut in one direction might well deserve to be commemorated with a couple of short ones (!!) in another. Seriously, however, seeing the depth of ignorance into which our Pharmaceuticals are plunged, it would be no bad plan to append notes of admiration to every dose of a medicine which, by giving an over-quantum, might become poisonous. This would sharpen their senses, and induce them to look twice before they leaped once. We should not then hear of a dose of tinct. opii being substituted for one of tinct. opii camphorata.

THE ARISTOCRACY OF THE BRAIN.

PHRENOLOGY, whether well or ill founded, has at least had the merit of making the human head an object of careful study, and of calling attention to many facts, which were previously either altogether overlooked, or very slightly attended to. Of its contributions in this way to the science of human nature, we had an interesting specimen in a phrenological journal. It is a communication from an eminent London hatter, containing the results of his own experience, and of two or three others in the trade, respecting the varieties of the human head presented by different classes of the community, and different provinces in the country. The subject is extremely interesting, and it is one upon which the testimony of the London wholesale hatter is of unquestionable value. They cover the heads of a great proportion of the provincial, as well as the metropolitan inhabitants, and as there are hats especially made for particular classes, such as sailors and livery servants, whilst the price of the others indicate the rank of the persons who wear them, there can be no doubt that they have it in their power to gauge the brains, not only of the single individuals, but of the various classes of the population. The paper, we ought to state, is entirely of a practical nature, and may rather be considered as a contribution to the natural history of man, than to phrenology.

"The brain," says the prince of living physiologists, "is the material organ of thought." "The volume of the brain is generally in direct proportion to the capacity of the mind." The only way of estimating the volume of

brain in a living person, is to measure the dimensions of the skull; every other means is uncertain. Setting phrenology aside then, and speaking simply as physiologists, it will be seen that we have two important facts upon the very best authority; first, that *size of brain is an indication of mental power*; and, secondly, that *the interior bulk of the head corresponds with the bulk of the brain*. Now the latter gives us the horizontal girth of the head, and this, though it does not include the depth, we know affords a pretty accurate measure of the actual magnitude. If Magendie speaks the truth, therefore, those persons have the means in their hands of *gauging* not only the *heads*, but, to some extent, the *intellects*, of all the people whose heads they cover.

Hatters' measure, the writer informs us, is the mean between the longer and the shorter diameter of the head. Thus, a hat, the cavity of which is 8 inches long by 7 broad, is said to be $7\frac{1}{2}$ inches' diameter, *hatters' measure*. The blocks for manufacturing hats are made on this principle, varying by 1-8th of an inch from 5 inches, the hatters' diameter of an infant's head, to $7\frac{3}{4}$ that of a man's fullest size. The varieties of size of English made hats range from $6\frac{1}{2}$ to $7\frac{1}{2}$ inches of this measure, the medium and most general size being seven inches. The range of the females heads is from $6\frac{3}{8}$ to $7\frac{1}{2}$. The reader must not think that the difference in heads is trifling because the interval seems to be small between these extremes; if he takes the trouble to calculate the cubic contents of two brains, of the diameter of $6\frac{1}{2}$ and $6\frac{3}{8}$ inches, he will find that the proportions are as 25 to 46, or that the one is almost twice as large as the other. The London hatters supply hats of all qualities for the inhabitants of the metropolis, but the coarse hats used in the country are chiefly made in Manchester. The writer of the article has therefore the means of judging as to the heads of both the rich and poor in London, and he has the means of comparing the heads of the upper and middle classes of London with those of the same classes in the country. Take seven inches as the medium size for all England, he finds, 1st, that the upper classes in London have heads above the medium size; 2ndly, that the lower classes have heads below the medium size; and, thirdly, that the middle classes have heads of a size intermediate to the two. We give the statement in his own words. "Commencing with London, a perceptible difference will be observed between the higher and lower classes of society. In the former, the majority are above the medium, whilst amongst the latter it is very rare to find a large head. This is easily proved by the different qualities of hats in requisition by each, in the manufacturing of which a distinct difference in the scale of sizes is observed. Taking the two extremes of society, this rule will be found invariable throughout the country, the middle ranks of

life forming a medium between the two. Establishments at the west end of the town, confined exclusively to the service of the higher circles, require more large hats in proportion than other hatters, whose trade is confined to the middle ranks; and again, the business with the lower class presents the same relation to the class above them, requiring a greater proportion of small hats than either of the other classes. These statements can be proved in a variety of ways. Take the average size of livery hats for servants, the scale will be found less than for their masters. The sizes observed in furnishing a regiment of soldiers are easily ascertained; seafaring men, and individuals connected with shipping and on the water, wear a peculiar hat, the dog's hair hats worn by carters, waggoners, and the labouring agriculturist, the round crowned shoulder-hats, in use by coalheavers, corn porters, &c, and the common plaited hats in general request by the working classes, present great facility for judging of general measurements for the lower orders, in all of which, as compared with the finest hat made, there is a striking and manifest difference. In the lower ranks of life, the majority are below the medium of 7 inches, and the higher classes of society above it. Not only difference of size is observed, but also a variation between the two classes exists in the circle of the head coming in contact with the hat, so as to influence the measurement. The upper portions of the head, comprehending the reflective faculties, ideality, and caution, come in contact, to increase the general circumference of the hat, in the higher classes of society; but the same effect is not observed in the lower walks of life; the circle round the head, in immediate connexion with the basilar region, the hat resting upon, or covering, the ear, will show that the size is more to be ascribed to that portion of the head than to the upper region. The slanting off of the lateral superior circumference much decreases the general measurement. The weavers of Spitalfields have extremely small heads; $6\frac{1}{2}$, $6\frac{3}{8}$, and $6\frac{1}{4}$ are prevailing sizes. In Coventry, almost exclusively peopled by weavers, the same facts peculiarly are observed.

"We have next to notice the provincial varieties. In the counties lying north and north-east of the metropolis, Hertford, Essex, Suffolk, and Norfolk, the head is smaller than any other part of the empire. In these counties, the medium size for all England is a full size, and a man in the maturity of life is often found with a head only as large as that of a boy of six years of age. In Kent, Surrey, and Sussex, the heads are larger. In the interior counties, proceeding towards the west, and in Wales, Devonshire, and Cornwall, they are above the medium London size; but the northern counties, Yorkshire, Lancashire, Cumberland, and Northumberland, produce a greater number of larger heads than any other part of England. The full

size, which in England is $7\frac{1}{2}$, is here enlarged to $7\frac{3}{4}$, and even 8 inches, and what is a large size in Essex and Hertfordshire is below the medium, and almost a small size in Scotland. The scale of measurement in furnishing hats for a Scotch regiment is larger than an English one. The writer acknowledges that he is not acquainted with all our provincial varieties, but he notices the fact, that in orders sent to London from Aberdeen, an unusual number of large sizes is required. The following anecdote is related between the Scotch and London heads of the lower classes:—‘A manufacturer at Manchester received an order from a London house to send off immediately a peculiar quality of hats. Having the same description of hats ready packed for Scotland, he sent off that packet promptly to oblige his London correspondent, without any regard to the sizes, to the metropolis. To the mortification of the individual to whom they were invoiced, they proved to be perfectly unsaleable, from the whole of them being very large in size.’”

These facts, in themselves, are unimportant; many will say it is of no consequence whether a man has a few ounces of brain, more or less; but when we connect them with the doctrine laid down, in such distinct terms, by the first phrenologists of the day, they evidently conduct us to some curious conclusions. Looking, for instance, at the varieties of fortune in the world, we are apt to regard life as a lottery, and to consider the wealth and the grandeur of one man, and the obscurity and poverty of another, as the result of positive laws, of accident, or of some causes little dependent on his personal qualities. But when we find the large heads at the top of society, the small ones at the bottom, and the middle ranks occupying the middle place in the cranial scale, we discover the operation of a principle in what seemed to be the mere effects of chance and destiny. We must apprise the reader, however, that bulk of head, according to phrenologists, is not to be received as a token of intellectual talent only. It may arise from a great development of animal propensities, of avarice, of the combative disposition, &c.; but in one shape or another it denotes *power*—that is, *power* of intellect, of sentiment, or of passion. Men of small intellect sometimes build up princely fortunes; but these men possess force of character; they act under some feeling, which directs all their powers into one channel, and that channel leads to wealth,—perhaps through meanness or crime. Persons of great intellect, again, often squander their patrimony, because their mental energy seeks employment in pursuits which consume their property, or, at least, divert their thoughts from the means of preserving it. The rapacious trader who amasses wealth may have as large a head as the philosopher who wastes his substance in schemes of ideal good; but the size will be developed in a different direction. The one

acquires riches; the other, perhaps, loses money and gains renown; but both distinguish themselves from the mass, and both, we may take for granted, have larger heads than those easy men who remain contentedly at the bottom of the social scale. The principle, in short, if sound, supplies us with a key to the revolution of fortunes in families. We see an individual rise in the world, and we call it chance or good luck; but it is merely a powerful brain mounting to its proper station. The descendants of this person intermarry with families of the same class, and thus a race of large brains is continued in the upper ranks, or they cross in a wrong direction, and, after riding in their carriages, perhaps change places with those who drove them. Were society founded on just principles, the *aristocracy of the brain* would predominate over every other; but many causes keep those down who are down; and a hundred devices have been contrived by rich men to prevent their heirs with small heads from sinking to the level for which nature designed them. Hence we may have many small brains in the upper ranks, and many large ones in the lower, though, on the great scale, there is apparently a correspondence between the size of the head and the individual station in life.

THE LATE M. DUPUYTREN.

THE funeral *cortège* of this distinguished professor was composed of members of the Faculty of Medicine in scarlet robes, of a deputation from the Academy of Medicine and the Institute, amongst whom were M.M. Poisson, Arrago, Thenard, Larrey, and Pariset; of a number of peers and deputies, artists, physicians, and of all the pupils of the school where the deceased lectured. It set out from the abode of the eminent dead, in the Place St. Germain l'Auxerrois. The place of interment was the romantic Pèze la Chaise, into which the great master's pupils drew the body.

Around the place of interment, the crowd, which was immense, formed a circle, and, in the midst of the most profound silence, M. Orfila, of the Faculty of Medicine, pronounced the following discourse:—

“Death has just struck a fatal blow, in taking from science, his family, and friends, Dupuytren, while still in the vigour and strength of life. The loss of one of the most illustrious surgeons of Europe will sound in tones of lamentation throughout the whole world. Those learned societies which were honoured by counting our colleague of their number, that great hospital where his genius shone with such *eclat*, and, if possible, still more the Faculty of Medicine of Paris, of which he was so distinguished an ornament, have now but to express their grief, and to mingle their regret over a tomb in which are

about to be deposited the remains of one so celebrated. Eloquent peers will undertake the task some day of proclaiming the scientific titles of Dupuytren, whose life, too short alas! was wholly consecrated to the teaching, practice, and perfecting of that art whose boundaries he extended.

"You will hear without surprise our academicians boast of the depth of observation, the enlightened knowledge, and elegance of style, which gave our late colleague so high a rank in the discussion of the most difficult questions. The physicians and surgeons of France will be unanimous in the sentiments of admiration he inspired, both by his numerous discoveries, and by the impulse which many branches of science received from his talent.

"Speaking as the organ of the Faculty of Medicine of Paris, I should, perhaps, chiefly point out all the services which he conferred upon it, by drawing a faithful picture of his services as a professor; but how could I undertake such a task, thus suddenly called upon to speak of one whose career was so brilliant, and while my mind, full of the melancholy event which has brought us together, has scarcely time to depict the leading features of his career.

"Dupuytren, Professor of the Faculty of Medicine of Paris, Member of the Institute, of the Royal Academy of Medicine, and many other learned societies, native and foreign, formerly Inspector of the University, Officer of the Legion of Honour, Knight of the Order of St. Michael and St. Wladimir, &c., was born at Pierre Buffiere, in the department of La Haute Vienne, the 5th of October, 1777. Devoting himself early in life to the study of medicine, he soon rendered himself remarkable in the eyes of his instructors by his continual application, and his happy disposition, and he speedily commenced the study of pathological anatomy and surgery.

"Gifted with a high faculty of eloquence and profound knowledge, he had from the commencement a numerous school to his private lectures, and took rank amongst them, destined to render the rank of a professor distinguished. He was appointed Professor in 1795, on the reorganisation of the school, and before he had attained his eighteenth year. In 1801 he obtained the place of chief in the anatomical department; in 1802, that of Assistant-Surgeon at the Hôtel Dieu; he was called in 1812 to fill the chair of operative medicine, vacant at the Faculty by the death of the celebrated Sabatier; finally, he became Professor of Clinical Surgery in 1815, and Chief Surgeon of the Hôtel Dieu in 1818.

"The greater part of these appointments were obtained after brilliant and painful *concours*, in which Dupuytren had to contend against men of transcendent merit, thus placed at the head of French medicine and

surgery. And never had the plan of election by *concours* a more eloquent advocate than our colleague. We all remember that in 1821, speaking in the name of the Faculty, in a solemn sitting he demanded, in a remarkable discourse, the re-establishment of this system, which had been suppressed for some years.

"The activity of Dupuytren as Surgeon of the Hôtel Dieu and Professor at the Faculty, has never been impugned. The General Council will long remember the services he rendered to the poor in the first hospital of Paris, and if it has constantly appreciated in the highest degree the devotion of Dupuytren to the sick entrusted to his care, and the attention which he lavished upon them, it can with difficulty console itself now for the loss which, in common with us, it cannot fail to deplore. On the other hand, the Faculty of Medicine has never seen the duties of the Professorship filled more assiduously. Always, both in his lessons and acts, his judgment was developed in the advice which he gave, and in its immediate application to the healing art. Above all, in his lectures on clinical surgery, of which he had the management for eighteen years, he acquired a reputation which can with difficulty, if at all, be surpassed.

"Frequently obliged to discourse upon diseases which he had hardly had time to examine, he always astonished his hearers by his accuracy of diagnostic; and, when he was compelled from necessity to recur to the last resource of surgery, who better than he knew how to conform to the maxim of Celsus with the view of diminishing suffering, avoiding accidents, and ensuring the success of the operation? If it were necessary now to recite all the medico-chirurgical questions discussed and elucidated by Dupuytren in his lectures, I should have but to trace out a table of the matters of which science is composed. I would above all recal to your recollection the instruments and operating processes which he either invented or brought to perfection. Can any one forget the lectures, original and rich in facts, on the arterial compressor, on venous hæmorrhage, on consecutive hæmorrhage in wounds, on the pathological anatomy of the fistulous passages, on lachrymal fistula, on the diagnostic of certain compound tumours of the scrotum, on complicated hydrocele of fibrous and cartilaginous degeneration, on nasal polypus, on strangulated hernia, on the displacement of the mucous membrane of the rectum, on the artificial anus, on the operation for cataract, lithotomy, excision of the elbow-joint, and a new proceeding by which the ulnar nerve is preserved, on resections in ununited fractures or those which were badly united, on fractures of the fibula and the apparatus invented for their treatment, on the congenital luxation of the femur, on wounds of arteries complicating fractures, on retraction of the fingers, on the spleen, on the lingual

nerves, on the motions of the brain, on the influence of the eighth pair of nerves in respiration, &c.

"It was not enough for Dupuytren to have given during his life proofs of his unalterable attachment to the Faculty and its pupils; he wished to be remembered by a last testimony of the interest he felt for it; and his last legacy will, while perpetuating his beneficence, make the memory of the benefactor imperishable. The generous disposition will be remembered with gratitude, which has given to one body of instruction a chair of pathological anatomy.

"It belonged to a distinguished and learned individual, who, by his researches, has so largely contributed to naturalise and propagate this science in France, to write a systematic course of instruction so long sought for by all lovers of science; known to the citizen who made so worthy, so noble a use of a fortune, which he owed to himself alone.

"Yes, dear colleague, your wish shall soon be fulfilled; your name shall be a thousand times proclaimed, a thousand times blessed from that chair, around which your powerful voice attracted the numerous auditory, which to-day, silent and in mourning, surround your bier. Future generations, like us, full of boundless gratitude, will lament your premature loss.—Adieu!"

After this discourse M. Larrey addressed the crowd in the name of the Academy of Sciences, and M. Parrisot, in that of the Academy of Medicine. M. Bouillaud also paid the tribute of his eulogy to the illustrious dead, and M. Royer Collard, in the name of the former pupils of the Hôtel Dieu, spoke in the same tone and spirit.

The last who addressed the auditory was M. Tessier, a pupil at the Hôtel Dieu, as follows:—

"Drawn together by grief and gratitude, let us give a tear to him who was our glorious master. In his ardour to instruct he sacrificed his life for the advantage of his pupils; and we who, from the last link of this long chain, have beheld him exhaust all the resources of wearied nature, and thus vanquished by suffering and disease leave with regret the scene of his labours. Another would have sought repose and health beneath the fine heaven of Italy; there he derived only new lights, which he hastened to communicate to us.

"Yet the sacrifice of his whole life was not enough; he wished to strengthen the ties which bound us to him; he has portioned science as he would an inheritance to his children.

"May his cherished and venerated memory be transmitted to generations to revere; may our gratitude be as enduring as our regret! Let him but live in our hearts, and our hearts cannot fail to find their noblest inspirations in the recollection of a life such as his."

M. Dupuytren lies buried not far from General Foy, a little to the left, between some tombs as yet without any inscription.

British Hospital Report.

ST. GEORGE'S HOSPITAL.

CASE I.—*Incarcerated Omental Hernia—no operation.*—But while strangulated hernia cannot be operated on too soon, there are frequently occasions for the exercise of judgment on the part of the surgeon in determining whether strangulation is actually present or not. An old and large intestinal hernia, for instance, frequently causes attacks of severe pain, constipation, tenderness of the tumour, sickness and vomiting, and yet no operation may be necessary in such case, the bowel being merely incarcerated, i. e. its functions impaired by its confinement, (generally from some imprudence in diet,) and yet the stricture not being tight enough to endanger the circulation in the protruded viscera; in which case the symptoms may be combated by appropriate means, and the temporary obstruction overcome. It is in cases of this description too that the operation becomes really dangerous, from the size of the tumour, and from the adhesion generally formed, and hence the propriety of that line of practice recently again recommended by Mr. Key, though so often lost sight of, viz. when strangulation actually takes place, to divide the stricture without opening the sac. With omental hernia again, although an operation is sometimes as urgently required as for intestinal hernia, yet there is no doubt, that, as a general rule, more room is afforded for the trial of such means as may succeed in removing the effects of the stricture without an operation. There is danger, indeed, of a portion of bowel being concealed in a mass of omentum, so that if from the symptoms there appears reason to fear such an occurrence, the surgeon should not trust to the feeling only of the tumour, but rather operate unnecessarily than incur the risk arising from delay; if, on the other hand, the symptoms are mild, he may wait till more urgent necessity for operation arises, and so, perhaps, avoid it altogether.

Ann Tenison was admitted under the care of Mr. Hawkins, Nov. 15th, 1833, with femoral hernia. She had rupture for six months, and the present tumour has continued down for the last fortnight, producing no pain or inconvenience till four days ago, when symptoms like the present came on, and after a few hours' suffering again left her; they returned, however, a second time, last night. The tumour is not very large, it is moveable and circumscribed, somewhat elastic, and has a large gland over it; it receives a slight impulse on coughing; it is very tender, and painful even when not handled,—she has also a good deal of pain in the back and around the umbilicus.

The bowels have been open since the tumour has been down, and she has no sickness; tongue white; pulse not very quick.

On her first admission she was placed in a warm bath, and had 20 ozs. of blood taken from the arm, and an unsuccessful attempt was made to reduce the tumour. Mr. Hawkins saw her in the middle of the day, and thought that the tumour was omental only—that the stricture was not very tight, from a slight impulse being still perceptible on coughing—that it was incarcerated, and not strangulated, and consequently that an operation would probably not be necessary; in which opinion the other surgeons who were in the hospital concurred.

A dozen leeches were applied over the tumour, an injection administered, and some aperient medicines given by the mouth. By this treatment the pain was reduced, and the bowels acted upon several times; she slept well during the night, and had no return of symptoms, and in a few days she was ordered to wear a truss upon the tumour, with a not very forcible spring, and the pad not so convex as usual.

CASE II.—Wearing a Truss upon an Irreducible Hernia.—In speaking of the propriety of wearing a truss over the omentum in the case just related, Mr. Hawkins said, that if care was taken not to use too great pressure, nor at first to continue it for too long a time at once, there was no danger of producing inflammation or other mischief in the part, and that the truss served effectually to prevent further protrusion, even if it did not succeed in reducing the hernia altogether. He then related the following case, to show that the same treatment was also applicable to intestinal hernia, and, being an interesting one, we preserved notes of the account.

A young gentleman, about thirteen years of age, was under the care of a physician for some time, in consequence of great disturbance of the bowels, and consequent derangement of the whole system, the cause of which was not evident till the boy complained of pain on one side of the abdomen, when it was clear that the testes had not yet reached the scrotum, and the pain was found to be just above the ring on one side. I was then asked to see him, and ascertained that without having come through the external ring, there was an effort to protrude on the least coughing or other exertion, the bowel apparently filling the inguinal canal on both sides. I then directed a double truss to be worn not pressing upon the external ring, where the testicle would have been compressed, but having a broad pad bearing upon the course of the inguinal canal. The boy immediately improved in health, and after wearing the truss for about a year, the testes had reached the scrotum, and the incipient double inguinal hernia was completely cured. Something of the same kind as this Mr. Hawkins

said was very common about the time of puberty, but the same boy was about a year afterwards an example of a circumstance which is comparatively very rare. He was observed to have very great irregularity in the action of the bowels, which were sometimes obstinately constipated for several days together, resisting the strongest purgatives, and only yielding at last to repeated doses of castor oil; the attack of constipation being frequently succeeded by diarrhoea for some time, during which the evacuations frequently showed a good deal of blood. Being under the care of the same physician, he frequently examined the abdomen, and I also saw him with the same object, but it was evident that there was nothing now wrong in the inguinal canals, and no complaint was made which led us to suppose that any other hernia existed to account for the severe symptoms he occasionally laboured under, and which had a good deal affected his health. At last, however, he fortunately received an accidental kick in the groin from a child, which drew attention to this part, and then a very small body was felt quite deep under Poupart's ligament, which was soft and slightly tender, and in which it seemed that our patient had occasionally heard something like the noise of air. This immediately excited our attention, as perhaps a femoral hernia, although, if so, it must be a very small portion of one side only of the bowel, not including the whole calibre of the canal, and scarcely equalling a common gland in size, and therefore, as it seemed, scarcely sufficient to account for the symptoms he had laboured under for several weeks, as no pain whatever had been felt in this part. Mr. Brodie also saw him with me, and said that he had never seen anything of the kind before. We agreed, however, that he should wear a slight truss over the part for some time. The effect of this was quite surprising, for the action of the bowels directly became regular and the health better. In a short time nothing could be felt in the part, and he soon after left off the truss without having since had any return of similar symptoms.

CASE III.—Operation followed by great Debility and Irritation.—Susan Dixon, æt. 44, admitted Oct. 22nd, 1833, under the care of Mr. Hawkins, with a femoral hernia of some size, turning upwards over Poupart's ligament. She states that she has suffered from a rupture for thirteen years, during which time she has never worn a truss; she has never been without a swelling in the groin, which has increased after any exertion, and she has suffered from frequent "bilious attacks." A year ago the rupture was strangulated, though without such severe symptoms as at present, and at that time the tumour was larger than it now is. She was seized with the present attack while scouring the floor on Saturday morning the 19th (three days and a half ago), since which time pain in the

bowels, vomiting, and excessive languor have continued almost without intermission till her reception in the hospital. During this time she was treated for inflammation of the bowels, with forty leeches, purgative medicines, and a large blister!—the hernia not having been discovered till this morning. On her admission she complained of great tenderness on the tumour and in the abdomen, especially in the part immediately around the tumour; there is very distressing and constant vomiting of dark brown substance, partly fecal in smell; the countenance sunk and sallow, and with an expression of great weakness and anxiety. Bowels not opened since Friday the 18th; tongue white and furred; pulse quick and weak.

The patient was kept in a warm-bath for a considerable time, but without a reduction being effected; Mr. Hawkins therefore proceeded to an operation. The steps of the operation were remarkable for the quantity of fluid contained in the fascia propria, and its exact resemblance to a hernial sac, especially as the real sac was so exceedingly thin and transparent, that when the fascia was opened and the fluid let out, it looked like the immediate peritoneal investment of the bowel. So distinctly was this part seen through the sac that many spectators thought the operator was cutting into the bowel, especially as it was some little time before Mr. Hawkins could satisfy himself of the exact nature of the parts, a great number of serous bands at the reflexion of the fascia propria adding still farther to the obscurity, as they looked exactly like adhesions between the bowel and the hernial sac, for there was no distinction in appearance between the outer surface of the real sac, and the inner surface of the fascia propria, both being as smooth as any serous membrane. When the real sac was finally opened, three or four inches of bowel were seen, which was very dark, softened, and echymosed, especially where the two folds of intestine were embraced by the stricture; the bowel being pulled down after the division of the stricture to examine its appearance, which showed very strikingly the changes produced by the stricture on the part below.

23rd. The operation being performed in the evening, she was left quiet during the night, and in the morning an injection was administered, which brought away a good deal of feces. The sickness was instantly removed by the operation, and had not returned. Pulse fuller, but weak and slow, and intermitting every 20th beat. Some beef-tea allowed.

R. Calomel., gr. iij. statim. Mag. sulph. ℥ij.
Aq. menth. pip. ℥iiss. M. 4tis horis sum.

24th. Streaks of blood in the evacuations procured by the medicine, which Mr. Hawkins

said he had several times seen where the bowel was much injured by strangulation, and he recollected one case in which more than a pint at time had thus come away, the patient, however, ultimately getting well. The pulse is more slow, and intermits much more frequently; the water requires occasionally to be drawn off by the catheter; abdomen tender and full, as if from flatulence.

To take a little white wine, and some brandy occasionally in water, and with arrow-root.

R. Sp. æther. nitros, ʒj. Mist. camp. ʒx.
M. 6tis horis.

Vespere. Feels stronger and better, but complains much of flatulence, amounting almost to tympanitis. P. intermits less frequently.

Ordered a large poultice of chamomile flowers in hot water, which gave great relief to the abdomen.

25th. Bowels open, a little blood still coming away; tympanitis continues, by which the abdomen is rendered of great size; pain and tenderness however less; P. stronger and fuller, and not at all intermittent; tongue clean; countenance less anxious. Mr. Hawkins ordered her to lie upon her side, which assisted in some measure in expelling the wind. Some relief was also given by the introduction of a large catheter into the rectum, through which some wind came away, which the sphincter otherwise retained. Most relief, however, was subsequently given by binding a broad flannel bandage pretty tightly round the abdomen. The wound dressed and looking healthy, though suppurating in part.

R. Haust. salin. ammoniat. ℥iiss.—
Trac. opii, ℥j. v. M. 6tis horis.

27th. Better; bowels open; pulse stronger; tongue clean.

28th. Sickness last night, otherwise much the same; tympanitis a little less; bowels not open, and some solid feces felt in the colon.

R. Ol. ricini, ℥j.
Rep. pil calomel, hss.

30th. Still a good deal of pain in the abdomen occasionally, to which a mustard poultice is frequently applied with advantage for a few minutes at a time. Wound open again, partly in consequence of suppuration.

Nov. 5th. She has gradually improved, and feels nearly as well as before the strangulation, being still, however, very weak and languid.

She has continued her wine and brandy, and as much food as she can take.

R. Infus. cascar. ℥iiss. Acid sulph. dil.
℥vi. Tr. gent. c. ʒss. M. ter die.

A sinus afterwards formed to some distance from the wound, which required to be laid open, but on the 28th she went out cured.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, Feb. 12, 1835:—John Gay, Wellington, Somerset; James Edward Beveridge, London; Henry Pilleau, —; James Thomas Blackmore, London; John Lewis Barillier, Leigh, Lancashire; Aris Henry Nourse, Birmingham.

MISCELLANY OF FACTS.

F. Society of Pharmacy at Paris.—M. Raymond has been elected President; M. Bussy, Vice-President; and M. Cap, Secretary, for the year 1835.

London Medical Society.—The Fothergillian medal for the year 1834 was awarded to Mr. Moon; the medal of the Society to Dr. Shearman. The anniversary oration will be delivered by Mr. Dendy, on the 9th of March.

Royal Institution.—The subject for the lecture on Friday, February 20, is the Respiratory System in the Animal Kingdom, by Dr. Graves.

How to mend a broken Basin.—Sir A. Carlisle is known to the frequenters of the Westminster Hospital as one of the most eccentric men in existence. While going round the wards he occasionally utters some good things; not a few of his remarks are, however, very trite and commonplace. In Percy Ward of the old hospital there was some time ago a man lying with a fracture of the pelvis. He had been in the house about three months, and was nearly well. Sir A. C., while walking through the ward, stopped near the bed, and asked the dresser what was the matter with him. A fractured pelvis was the reply. What business has he here, then? You should send him to the *china-merchant*, he is the proper person to mend a broken basin. No occasion, Sir Anthony, it is already rivetted.

William Lynn, Esq., Consulting-Surgeon to the Westminster Hospital, has resigned his seat at the Court of Examiners of the Royal College of Surgeons. This venerable surgeon, now in his eightieth year, has recently experienced several attacks of an apoplectic character, which have incapacitated him for active service. He will be succeeded by Sir B. C. Brodie, although the junior member of the Council. He takes the seat because the bye-laws make the Sergeant-Surgeon to the King eligible in preference to all others.

APPOINTMENTS.

Naval.—Mr. Price, surgeon to the Royal Sovereign yacht, and to relieve Dr. Donely, surgeon R.N., in the charge of the medical marine depot at Pembroke.

Military.—Assistant-Surgeon Foss, of the 44th Foot, has exchanged with Assistant-Surgeon John Dempster, M.D., of the 38th Foot. Assistant-Surgeon Thomas Coke Gaultier, M.D., of the 55th Foot, has also exchanged with Assistant-Surgeon John Hartley Sinclair, M.D., of the 48th Foot.

Resignations.—Mr. Wm. Fitch, surgeon of the Kent and Canterbury Hospital. Mr. Miller, apothecary to the Bloomsbury Dispensary, Great Russell-street. Mr. —, examining surgeon and apothecary to the Marine Society's ship off Deptford. Dr. Holroyd, physician to the Marylebone Dispensary, Welbeck street, Cavendish-square.

DEATHS.

Dr. James Bryce, assistant-surgeon to the E. I. Company's service at Kyouk Phoo. Mr. David Stewart, surgeon of Kirriemulr, Scotland. Dr. Robt. Tindale, at Ocotol, near the Real del Monte, Mexico. Dr. John Barry, of Henrietta-street, Cork. Mr. Edward S. Bonthoon, of Rankeillor-street, Edinburgh, surgeon. Assistant-Surgeon Charles Rankin, of his Majesty's ship Racer, stationed in Jamaica.

LITERARY INTELLIGENCE.

The "*Clinique Medicale*" of Dr. Andral, Professor to the Faculty of Medicine of Paris, &c., condensed and translated into English, with practical remarks, principally regarding the treatment of disease, extracted from the writings of the most distinguished medical authors. By Dr. SPILLAN, M.D., Fellow of the King and Queen's College of Physicians in Ireland.

Every thing of real practical value in the original French has been scrupulously preserved in the present English edition, those cases only having been omitted which were not calculated to excite the interest or reward the attention of the British reader. The great advantage of thus possessing, in the condensed form of *one volume*, a *Complete System of Medical Pathology*, which in the original occupies five volumes, is sufficiently obvious. The work will be published in *four parts*. The first part will appear in the middle of April, and the remaining parts at intervals of two months each.

Preparing for publication, by subscription, in folio, *Fractures of the Extremities*, exhibited in twenty plates, showing the Causes of Displacement, with an explanation of the Appearances and mode of Treatment. By GEO. HIND, M.R.C.S.L., formerly House-Surgeon to the Middlesex Hospital, and late Curator of the Museum of Anatomy of the University of London.

CORRESPONDENTS.

Singultus.—The facts he complains of are in a fair way of being remedied; a little patience will do a great deal.

Inquirer.—Dr. Waller and Dr. Blundell are the two chief supporters of transfusion.

X. P.—A letter has been forwarded to his address.

A General Practitioner.—There are two tinctures of the lobelia inflata, one spirituous the other aetherial; the latter only possesses the virtues of the plant, the former is useless.

Errata in our last.—Page 88, for "Russian," read "Prussian."

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

LECTURES

INTRODUCTORY TO THE COURSE OF THE
INSTITUTES OF MEDICINE,

DELIVERED BY

ROBERT J. GRAVES, M.D.,

King's Professor, Dublin.

LECTURE XVII.

GENTLEMEN,—At the conclusion of my observations on the appetite for food, I spoke of the various modes adopted by mankind to allay the sensation of hunger, and of the extraordinary effects produced on the system by long deprivation of food and drink. In considering the length of time man may subsist without taking any solid aliment, it is remarkable that persons labouring under various forms of disease bear the want of food much longer than those in the full enjoyment of health. Thus we see every day instances of persons in fever taking no nourishment for weeks except a little whey or barley water. The same thing is observed in certain forms of gastric disease, the patient goes on sometimes for months harassed by continued vomiting and rejecting his food almost immediately after it has been swallowed, yet it is very rare to find such a person dying of starvation.

A knowledge of the symptoms which arise from want of food is of considerable importance in the treatment of fever and other affections, in which the patient remains for a considerable time without taking any kind of nutritious aliment. There is a certain advanced stage of fever, when a degree of delirium is present, when the patient's pulse is quick, his eye suffused, his tongue dry, his sensibility to external objects either impaired or deranged, his watchfulness persistent, or only interrupted by an imperfect slumbering with half-closed eyelids, when every organ is in a morbid condition, and every function vitiated or suppressed. At this period of an almost mortal struggle with disease, the dry tongue, the blood-shot eye, and the cerebral excitement, are apt to betray the practitioner into the error of supposing that the

existence of inflammation in the brain or stomach is the only thing capable of accounting for the alarming train of phenomena present, and with this impression he has recourse to leeching, blistering, and other modes of depletion. But the mischief is not to be obviated in this way; the symptoms assume a more intense and threatening character, and the patient sinks. A far more reasonable and more successful practice is to endeavour to calm the nervous irritation by the employment of opiates, and to sustain the sinking powers of life by the judicious administration of light nutritious food and wine. Often have I under such circumstance seen the tongue become moist and clean, the conjunctivæ grow clear and pale, the delirium subside, and tranquil refreshing sleep return, under the use of wine.

I have mentioned that one of the effects of starvation was inflammation of the stomach and duodenum. In many cases of fever, where gastric or gastro-enteric disease is said to exist, and in numerous instances of dyspepsia supposed to be connected with an inflammatory condition of the mucous membrane of the stomach, the treatment adopted by many practitioners on the continent and by some in this country, is perpetual leeching and a rigorous diet; in fact, besides constant local depletion, a modified system of starvation is enforced. Now the gastro-duodenitis of fever is, in a vast number of cases, nothing more than a species of indigestion, with pain in the stomach and tenderness on pressure, and, in such cases, the debilitating effects of constant leeching, combined with the want of food, have brought on the very symptoms which they were intended to remedy. In concluding this brief notice of a very important subject, I would beg leave to refer you to Piorry's work, in which you will find some excellent remarks on the *diète absolue*.

With respect to the nature of their peculiar aliment, animals have been divided into frugivorous, graminivorous, carnivorous, and omnivorous. Among the latter man is properly classed. Man and several other animals have been called omnivorous, because vegetable matters, fruits, and flesh are equally suited for their nutrition.

A great deal has been said and written about the diet most suitable for man. Formerly it was the fashion to extol the numerous advantages attendant on a frugal fare; it was asserted that the more simple the diet, the more healthy; that vegetable food was more conducive to longevity than animal, and that repasts consisting only of the fruits of the earth and the water of the spring were essential to a vigour of body, clearness of intellect, and peace of mind. Modern investigations have overturned this beautiful and poetic system of dietetics, by proving that it has no real foundation in nature. In the first place it appears, when we study the conformation of the human body, and the peculiar structure of the organs employed in the various processes of digestion, we find that man is evidently destined to be an omnivorous animal. If we look to his teeth, we find them to be adapted to the mastication of all sorts of food, whether fruits, vegetables, or flesh. Again, when we examine his stomach and intestines, we find that he has neither the short and simple intestinal tube of the carnivorous, nor the long and complex one of the graminivorous animals, in fact, that the stomach and intestines are calculated to derive nutrition from every species of food. In addition to this, man is the only animal that prepares his food, submitting the various articles of diet to processes which at once render them agreeable to the palate, and easily digested; in other words, man, prompted by instinct, and assisted by reason, is the only cooking animal, the only one capable of modifying the properties of the various alimentary matters used by different classes of animals, so as to render them suitable to his own nutrition. Hence the various operations of cookery are universally known, and have been practised from the most remote era, and there is no instance of a tribe or nation existing at any period and unacquainted with the modes of preparing food. It is true that until the arrival of Europeans, the inhabitants of New Holland were ignorant of the process of boiling water; but they were perfectly well acquainted with the modes of preparing food by roasting or broiling.

The opinion of the poets and philosophers, that a simple vegetable diet was calculated to produce, not only greater clearness of intellect and length of life, but also greater bodily vigour, does not seem to be founded in truth, for it has been established, that persons living on a mixed diet and using a large proportion of animal food, enjoy equal, if not superior, longevity, and exhibit much more intellectual energy and bodily strength. That persons living on a mixed diet, and using a large proportion of animal food, are stronger than those who subsist chiefly on vegetables, is proved by the experiments made with the dynamometer by M. Peron. He selected seventeen Frenchmen, fourteen Englishmen, fifty-six men of the island of Timor, seventeen New Hollanders, and twelve of Van Diemen's Land (the three latter living chiefly on vegetables), and, having

ascertained their respective strength, he gives the mean results in each case. From the details it appears, that in point of strength the English rank first, next the French, then the inhabitants of Timor, and, lastly, the men of New Holland and Van Diemen's Land. In the two latter, the greatest strength of the arms was equal to 62 kilogrammes; in the English trials the greatest was 83, and the smallest 63. In the power of the loins, the highest among the New Hollanders was 13 myriagrammes; the lowest of the English was 12.7, and the highest 16.3. Thus we see the English, who consume a considerable proportion of animal food, are stronger than the French, and the French than oriental nations, who subsist chiefly on rice.

The idea of living on a purely vegetable diet originated in many countries from a notion that it was wrong and unlawful to deprive animals of life, for the purpose of supplying bodily wants which could be otherwise gratified, and it is the peculiar boast of those who profess this doctrine, that it is in strict accordance with the dictates of a refined and comprehensive humanity. But the discovery of the microscope has unfortunately stripped this doctrine of its most amiable character, by showing that, in chewing his crumb of cheese, the Pythagorean murders thousands of living beings, and in swallowing his cup of water deprives myriads of life.

You may ask why do I dwell on this subject? Because I am persuaded that many of the opinions held at present with respect to diet, are founded on false theories. I am persuaded that simplicity of diet is too much insisted on in the treatment of dyspeptic and other cases. I believe that simplicity in prescription, and simplicity in diet, have been carried too far. It is now well established by theory as well as by experience, that in prescribing we accomplish our object with more certainty and effect by combining several remedies, than by limiting our practice to the employment of a single therapeutic agent. It is the same thing with respect to diet. I am not an advocate for luxurious living, nor would I recommend that excess of variety which characterises the meals of the gourmand, but I think it is wrong and injudicious to make persons live on a single dish. There is a physical as well as a moral objection to it. The custom of partaking of various kinds of food is not easily overcome, the patient grows tired of his solitary chop or beef-steak, and feels no gratification in eating. Now, *cateris paribus*, whatever is eaten with a relish is more easily digested than that which is swallowed with indifference or dislike. Many persons assert that a meagre and scanty diet, in quantity much smaller than the appetite demands, and consisting merely of a little bread and gruel, is calculated to promote longevity, and maintain intellectual as well as bodily vigour. Gentlemen, I do not believe this. I have no intention of encouraging gastronomic ingenuity, but

I must confess I look on such simplicity in diet as an error against nature. It is an error against that principle which has made man press into his service so many individuals of the animal kingdom, and convert so many vegetable substances to the purposes of his own nutrition.

Let us consider for a moment those articles which are prepared by the hand of nature for the food of man and other animals. Let us look to that substance which forms the only nutriment of the young of all the mammalia, milk. Is milk a simple substance? No; it is a compound of saccharine, caseous, oily, and albuminous principles; a substance which the simplifiers of diet would say was too complex to be presented to the stomach, and yet it is that which nature has destined for the only support of a vast number of animals at the tenderest period of existence. Again, let us look to the food prepared for graminivorous animals, and we shall find that nature has been here equally varied and equally bountiful in her productions. It would be impossible to get a pasture in which the grass is restricted to a single species; in most pastures there are from fifteen to twenty different kinds, differing in the nature and combination of their vegetable principles, and having separate effects on the economy. Had nature limited the horse or the ox to a single species of grass, this profusion would not have existed; but it was never intended that man and his fellow animals should adhere to a strict simplicity of diet. On the contrary, I feel fully convinced that a certain variety in food is highly essential to the restoration or maintenance of health. This opinion may appear strange, but I can aver from extensive experience, that the physician who treats the valetudinary and dyspeptic on these principles, will be much more successful than he who restricts his patient to a single dish.

The researches of experimental physiology have elicited a number of important facts bearing on the question of simplicity in diet. M. Magendie, as you all know, has shown that dogs fed on sugar alone become after a certain time weak and emaciated, lose their sight from ulceration of the cornea, and eventually die. Again, M. Raspail, in his late work, *Nouveau Système de Chimie Organique*, has shown that gluten, the nutritive principle in plants, will not sustain animal life. Neither sugar nor gluten is alone capable of supporting life, but, if you combine them, they afford a wholesome and nutritious aliment. The human body is not simple; it consists of a great number of fluids and solids, which differ essentially in their nature and chemical composition. Into this composition a great number of elementary principles enter, and is it not, then, reasonable to suppose that a variety of materials will be required? If we were to reduce diet to such a state of simplicity as to diminish the number of the elementary principles which enter into the composition of the solids, I do not think

the nutrition of the body could go on. It is true, that nature is able to manufacture a great many different elements from very few materials, but a certain number of principles must exist to enable her to prepare the compound which she employs for supplying the various wants of the system*.

"In France, most substances are exposed, through the medium of oil and butter, to a temperature of at least 600° Fah., by the operation of frying or some analogous process. They are then introduced into a macerating vessel with a little water, and kept for several hours at a temperature far below the boiling point (212°), not perhaps higher than 180°; and by these united processes, properly conducted, the most refractory articles, whether of animal or vegetable origin, are reduced, more or less, to the state of pulp, and admirably adapted for the further action of the stomach. In the common cookery of this country, on the contrary, articles are usually put at once into a large quantity of water, and submitted, without care or attention, to the boiling temperature. The consequence is, that most animal substances, when taken out, are harder and more indigestible than in the natural state, for it is well known that albuminous substances (as, for example, white of egg) become the harder the longer they are boiled."

An excellent illustration of the principle laid down by the Reviewer is afforded by the liver and the kidneys, each of which becomes remarkably harder in consequence of the common methods of cooking. There can be little doubt that the livers destined for the food of dogs are rendered much less palatable and digestible by the pains the unwilling cook is forced to bestow on them.

"These observations are often of the utmost importance in a medical point of view. When the powers of the stomach are weak, a hard and crude English diet (such, for example, as half raw beef-steaks so frequently recommended) is sure to promote much discomfort by promoting acidity, while the very same articles, well cooked upon French principles, or rather the principles of common sense, can be taken with impunity, and easily assimilated.

"It has been remarked, on the authority of one of our ablest physicians, that our principal alimentary matters may be reduced to three classes, of which sugar, butter, and the white of egg, are the representatives. *Now, it is a curious circumstance, that milk, the only article absolutely prepared and intended by nature as an aliment, is a compound of all the three classes; and almost all the graminaceous and herbaceous matters employed as*

* The preceding observations on diet were given in a lecture delivered last November. Those which follow are taken from the 104th No. of the Quarterly Review, which I did not see until long after; they remarkably corroborate my views.

food by the lower animals contain at least two, if not all the three. The same is true of animal aliments, which consists at least of albumen and oil. In short, it is almost impossible to name a substance, employed by the higher animals as food, that does not essentially constitute a natural compound of at least two, if not all three, of these great principles of alimentary matter." * * * *

"It would seem that various food is the most wholesome for man; that he thrives best upon a proper admixture of vegetable and animal diet. The Brahmins, who feed solely upon rice, are not long-lived, and are endowed with feeble constitutions; on the other hand, the Esquimaux are obliged to mix saw-dust with their train-oil." * * *

"But it is in the artificial food of man that we see this great principle of mixture most strongly exemplified. Dissatisfied with the productions spontaneously furnished by nature, he culls from every source, and forms in every possible manner, and under every disguise, the same great alimentary compound. This, after all his baking, roasting, and stewing, &c. how much soever he may be disinclined to believe it, is the sole end and object of his exertions. Even in the utmost refinement of his luxury the same great principle is attended to; and his sugar and flour, his eggs and butter, in all their various forms and combinations, are nothing more or less than disguised imitations of the simple elementary prototype—milk *."

To conclude this part of our subject, I may observe, gentlemen, that even water, as nature offers it for our use, is by no means unadulterated and free from what the ignorant would call impurities; as, whether we draw from the spring or the river, it contains a great variety of salts, gases, &c.: when perfectly purified by distillation, it becomes at once unpalatable and indigestible!

So far as to the general principles of diet. A few facts may be here mentioned with respect to some particular articles of food. It is a curious fact, that occasionally certain principles become developed in chocolate and cocoa when long kept, which render them injurious to the sight. Persons who have used these substances (but particularly cocoa) for a long time, are apt, under such circumstances, to get weak sight and amaurosis. Chicory also brings on amaurosis, and this substance is not unfrequently used to adulterate coffee. Rice also appears to be bad for the sight, particularly when used in a damaged state; and it has frequently been remarked, that the number of blind persons in the East is very great. Dr. Tytler has gone so far as to assert that the Oriental cholera depends on spoiled rice; this, however, is not borne out by facts, for we have had it raging here among a population, the majority of which never even tasted rice.

Having spoken of simplicity of diet in re-

spect to food, let me now say a few words concerning drink. I have already stated that it was my conviction that too much simplicity in the use of solids was bad; I have the same objection to make with respect to fluids. I believe that water alone was never destined to be the exclusive beverage of mankind. Nature has prepared milk for his use as well as water; and in tropical climates she has furnished various fluids from plants to refresh his strength and cool his burning thirst. We also find reasoning man, in every country of the globe, manifesting a tendency to express various juices from plants for the purpose of giving variety and zest to his drink. If we turn to the records of the most remote antiquity, we find that in the earliest periods of society, in the days of primitive innocence and patriarchal simplicity, the art of making fermented liquors was known and practised. The use of wine is of very high antiquity among the eastern nations; and we find the early Egyptians using a fermented liquor from grain, which was termed *barley wine*, and was drunk by the poorer classes. Among the infinite ramifications into which the human family is divided, we do not meet with any tribe so barbarous, or so insulated from commerce with the rest of mankind, as to be unacquainted with some mode of giving variety to their ordinary drink. There can be no doubt that nature never intended water to be the only beverage of civilised man; and I am confident that if the whole British nation drank nothing but water for the next twenty or thirty years, they would not be as fine and as vigorous a people as they at present are. Indeed I have but little doubt that if all mankind were to become water-drinkers, they would, in the course of a few generations, realise the poetic idea of the degeneracy of the human race. Of this, however, there appears to be but little apprehension, for the tendency to mix fermented and other liquors with their ordinary drink is universally diffused through the mass of mankind. Here, however, reason must control the appetite; and though it was intended that man should use fermented liquors as well as cooked victuals, still he must recollect, that, like other boons, these must be enjoyed in moderation, and a wholesome medium observed. The abuse of fermented liquors is attended by a numerous train of evils; and hence our Temperance Societies have a highly laudable object in view in endeavouring to control the appetite for drink; but, in pushing matters too far, they have overshot the mark, and thus the arbitrary nature of their rules has prevented their doctrines from being more generally received and adopted. The total interdiction of spirits in every shape has deterred the lower classes from joining their ranks. It is true, that the abuse of spirits is a mighty evil,—that it is the great and destructive poison which operates in the veins of the nation. This, however, should not totally forbid its proper use, for, in small quantity, it appears

well suited to this climate, and to the constitutions of this country, and even possesses advantages over wine.

The constitution of different individuals differs in nothing more remarkably than in the tolerance of spirituous liquors, some being affected by a very small quantity, while others are able to indulge in immense potations with impunity. I lately attended a very fat Englishman, of large stature, who was remarkable as an excellent man of business, and had for many years directed the very complicated affairs of a large factory in the neighbourhood of this city. His intellect was always clear, and he was constantly employed in revising the accounts and superintending the expenditure of an establishment, in which there were five or six hundred operatives. While thus employed he drank a glass of brandy every three quarters of an hour, so that his daily allowance varied from eighteen to twenty glasses! This practice he had continued for many years without any apparent injury to his constitution. The break, however, came at last, and he died of dropsy at the age of 35.

Among savage nations the introduction of ardent spirits by Europeans, has been productive of the most disastrous consequences, and it is to be feared that the supply is facilitated in many cases for the very purpose of producing the moral degradation, and national ruin, that have too often followed their introduction. The most remarkable instance of a savage toper that has been recorded, is mentioned by Moore, in his Account of his Travels in Africa. "The King of Barsally, as well as his attendants, are zealous Mahometans, and whenever he was not completely intoxicated he prayed most fervently. Far from thinking, with others of his persuasion, that it was worse than death to taste brandy, or other strong liquors, he considered it almost a deadly evil to taste any thing weaker. His usual course of life was to rise at night and to drink till towards day-light, then eat and go to sleep till near sun-set. At that time he rose, and, having again drunk copiously, went to sleep till midnight. His insatiable thirst for brandy kept both his subjects and neighbours in a state of perpetual terror: when he stood in need of a supply of this indispensable article, he immediately sent to the managers of the company at James's Fort, requesting that they would dispatch a cargo to be exchanged for slaves, a call which these worthy personages always obeyed with the utmost alacrity. Then the king marched suddenly to a neighbouring town, set fire to three parts of it, and stationed his guards at a fourth, who seized the inhabitants as they attempted to escape. If he was not at war with any of his neighbours, he then (says Moore) falls upon one of his own towns, and uses them in the very same manner."

Tea and coffee have also their peculiar effects on the system. These, however, exhibit a considerable difference in different individuals. One person uses large quantities with

impunity, while another, who takes a moderate share only, leads a wretched life. It is a fact, that many persons, labouring under headach, tremors, bad sleep, and indigestion, may be cured by leaving off tea and coffee, and using instead some table-beer or porter. By substituting these (the latter in the case of English stomachs, the former of Irish), and by giving solid and nutritious food (without confining the patient to one dish), many cases of obstinate dyspepsia have been cured.

With respect to the subject of diet, many curious and important facts may be learned from a perusal of one of the most extraordinary books of modern times, the *Life of Caspar Hauser*. This unfortunate youth, whose birth has been a riddle, and whose death has been a mystery, subsisted until he was upwards of sixteen years of age on bread and water. The extraordinary physiological phenomena connected with this young man's intellect, senses, and bodily functions when exposed to the full influence of physical agents, have been ably and accurately detailed by his biographer, M. Feuerbach. There is one very curious circumstance in his case which deserves notice. He laboured under a constant thirst and drank enormous quantities of water. This habit was not of recent origin, but had existed as long as he could recollect. As soon, however, as he got accustomed to warm drink, his thirst diminished, and in the course of a few weeks the mere addition of heat to his drink had enabled him to satisfy thirst with the ordinary quantity.

Among the articles of food used as mere condiments, or for the purposes of preserving meat, salt is one of the most general. It would appear, that man accustomed himself, at a very remote period of antiquity, to the use of salt, on account of the necessity of preserving the flesh of animals in warm climates, as well as for the purpose of rendering his food more palatable. Many other animals also exhibit a strong liking for this substance, and seek it with extraordinary avidity. In North America buffaloes are known to travel great distances in quest of salt, and pigeons fly hundreds of miles to gratify this desire at the salt springs. In Central Africa this propensity leads to annual migrations of the cattle, which travel in droves for several days, until, arriving at a salt spring, they commence drinking the water with great eagerness and apparent relish. I cannot explain why these animals seek for and feed on salt at certain seasons of the year, but it is reasonable to conclude, that an instinct so strong and so persevering was not given in vain.

There are many interesting details connected with the derangement of health resulting from the want of salt, in persons long accustomed to its use, and we have also several curious facts with respect to the effects produced by habitually using salt in large quantities, or rather by the long continued use of salt provisions. In the latter case scurvy is the consequence, in the former a distressing

train of nervous and dyspeptic symptoms. In certain parts of Asia and Africa, where no salt can be procured, European travellers have suffered very great distress. With scurvy you are all well acquainted; it exists generally among sailors who have subsisted for a long time on salt provisions, and may be frequently seen among the poorer class of people from the same cause. It is most generally combined with an enfeebled habit of body, purpura, and dropsy. Among the artisans and roomkeepers in Dublin, who live chiefly on salt meat and fish, you will meet many persons who are feeble, pale, asthmatic, and subject to hemorrhages from the nose, gums, stomach, and bowels, with a tendency to anasarca and dropsical swellings.

With respect to condiments, as salt, pepper, mustard, &c. &c., it may be observed, that they have been very extensively used for a considerable space of time, and in moderation are productive of good effects. They prevent flatulence and promote digestion, but, as in the cases of spirits, when used to excess, they produce irritation of the digestive system. I have lately seen a case of chronic inflammation of the stomach and indigestion from taking a large quantity of Cayenne pepper. It produced severe bowel complaint, with tormina and bloody stools, followed by dyspepsia, under which the patient has been labouring for the last seven months.

I need scarcely observe, that food must be varied according to the occupation of the individual. Persons who take violent exercise in the open air require a strong and highly concentrated nutriment. The natives of the Pampas, who are constantly on horseback, and ride enormous distances, fatiguing several horses in a day, are in the habit of using what is called jerked beef, which consists of the muscular parts of cows or oxen, cut into thin stripes and dried in the sun. This forms a highly nutritious food, and Captain Head gives an interesting account of the surprising fatigue he was able to undergo while living on dried beef and water alone.

You will find, also, that sleep is supplementary to food, and the more sleep a person takes the less food he requires. The man who sleeps till nine o'clock seldom eats so hearty a breakfast as the man who rises at five. In the same way soldiers when engaged in night duty, and sailors when they have additional watches in bad weather, require an extra allowance of food and drink. You will meet with many interesting facts bearing on this point in Captain Parry's account of his attempt to reach the North Pole, and from which it appears that he was obliged to increase the allowance of food during that arduous period of the expedition, when the men had scarcely any sleep for many days in succession.

I had intended to make some observations on the stature, strength, and swiftness of the human race, but as the period allotted to this part of the course has expired, I must neces-

sarily be brief, and refer you to books for further information. With respect to stature, it is a curious fact, that from the most remote ages there has existed a singular propensity among mankind to underrate the size of their contemporaries, and to represent them as diminutive when compared with preceding generations. You will find traces of this opinion in the works of various writers from the time of Homer and Hesiod down to the present period; indeed, this is carried so far in the ancient authors, that whenever an old man speaks of the stature and physical powers of men, it is only for the purpose of descanting on the degeneracy of the human race, and referring, with much complacency, to the feats of superior strength and activity which he witnessed among the tall and athletic companions of his youth. That this opinion is not borne out by facts is proved by the remains of human bones found in the most ancient burial places, and by the Egyptian mummies, as well as by pieces of ancient armour, and by an inspection of the buildings designed for the abode and accommodation of mankind in former ages. This is further strengthened by a reference to the general size and stature of those tribes or nations who have never assumed the habits of civilised society, and who still live in a condition analogous to that of the earlier races of mankind. Thus, if we examine the native Americans, Africans, and South Sea Islanders, we shall find that they do not exceed us in stature; indeed, it has been generally observed that they are inferior in height to Europeans.

The accounts given of persons of gigantic stature who lived in past ages, have been proved by the accurate researches of modern science to be nothing more than fables founded upon the anatomical error of mistaking the bones of large animals for human remains, together with the common propensity to believe and report what is marvellous. All the supposed gigantic remains have turned out to be those of the elephant or some other large animal, and there is no authenticated example on record of a man higher than eight or nine feet. The modern instances of extraordinary height are, with very few exceptions, observed among the nations of Europe. Thus a Swede, in the King of Prussia's Guards was eight and a half feet; a German in the service of Duke John Frederick, of Brunswick, Hanover, measured the same; Gilby, a Swede, eight feet Swedish; Reichard, a German, eight feet, three inches; and O'Brien, an Irishman, eight feet, four inches. Among the ancients, the Germans were remarkable for their great stature; and, among the moderns, the inhabitants of Patagonia, who are in general from six to seven feet in height.

With respect to the strength of men, the same opinions have prevailed as with regard to his size and stature. It has been asserted, that the men of the present race have degenerated from the vigour of their ancestors; and it is also maintained, that civilised man is

quite inferior in strength to the savage who roams the wilds of Africa or America. Neither of these opinions appears to be well founded; bodily strength is the result of health, exercise, and a proper supply of wholesome food; and hence the *cæteris paribus*, the well-fed classes of a civilised community may be reasonably expected to surpass the miserable savage who frequently labours under want of food and other privations.

With respect to feats of activity in the human race, many have been recorded, and much has been written, concerning the swiftness and endurance of various individuals. In this respect the Negro race does not appear inferior to whites, not to mention what has been observed by modern travellers in Africa. I refer you to the accounts given by historians of the games held at Lisbon in 1489, to celebrate the baptism of the African King Bernay. "The Portuguese monarch celebrated this event by all the exhibitions which were fashionable in that age—bull feasts, feats of dogs, and puppet-shows. Bernay took this opportunity of displaying the prowess of some of his own followers. As the principal Portuguese cavaliers were making a display of their horsemanship, he called several negroes, who, on foot, followed and kept pace with the swiftest of these animals. The same negroes leapt off a horse at full gallop, and, following, again mounted with the same promptitude as if he had been standing perfectly immovable*."

When Alexander Selkirk resided so long on an uninhabited island, he gradually acquired so much swiftness as to be able to outrun and catch the wild goats.

With respect to feats of strength in modern times, the most surprising on record are those performed by Thomas Topham, about a century ago, and of whose performances an interesting account is given in Brewster's Letters on Natural Magic. This man's strength was prodigious, being equal to 800lbs, which is double that of very strong men. This leads me to speak of gymnastics, as connected with the development of strength; and, without entering into any lengthened discussion of the subject, I may observe, that however desirable such a mode of exercise may be to those who cannot take proper exercise in any other way, they are, generally speaking, totally unnecessary for the education of the body. Natural gymnastics are constantly and extensively practised by every healthy boy and girl, unless prevented by an improper system of education. Among females it too frequently happens that wholesome exercise is neglected; and you will find, in Dr. Arnott's Treatise on Physics, a detail of the various expedients resorted to by those who educate girls to prevent them from enjoying the free and healthy use of their limbs. Boys, fortunately, are not subjected to the same restraints; and hence, if an anatomist were to visit one of their play-grounds, he

could scarcely point out a single muscle which is not repeatedly exercised during the brief space allowed for their recreations. Gymnastics certainly encourage the development and increase the power of certain muscles; and persons who exercise their muscles in this way will be so far stronger than others. But it does not follow that such persons are healthier than those who take ordinary exercise. It is a remark as old as the time of Hippocrates, that persons who practise gymnastics are in a dangerous state of health. They increase the power of the muscular system, but, if they do, it is at the expense of the rest of the body; and it was remarked of old, that the athlete and others who practised gymnastic exercises were subject to violent disorders, and were seldom long-lived.

It is difficult to prevent boys from taking too much exercise. During the period of growth great fatigue injures the general health. But even when gymnastic exercises are so managed as to avoid this inconvenience, and when they succeed in imparting to the boy an extraordinary degree of muscular development, I am perfectly convinced that the natural adjustment of the functions is thus prevented; for however well fitted the frame of youth may be for feats of agility, nature has not adapted it for strength, the attainment of which she defers until the period of growth is passed; and consequently her plans are deranged when muscular strength is artificially and prematurely obtained.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XX.

Mechanism of Parturition.

GENTLEMEN,—Before I describe to you the mechanism of parturition, or the manner in which the child passes through the pelvis and external passage during labour at the full term of pregnancy, I must call your attention to the peculiarities which adapt the female pelvis for this process; for upon an accurate knowledge of these points will in a great measure depend the correctness of your diagnosis and practice in many of the cases of difficult labour, which you will occasionally meet with in after life. Unless you are well acquainted with the dimensions of the female pelvis, it will be almost impossible for you to follow me in my description of the different presentations of the child, and the course which it follows during its passage through the pelvis.

"In comparing the adult female pelvis with that of the male we observe, that in the latter

* Di Barros, iii. 7.

the promontorium sacri projects more toward the symphysis pubis; in the former less so, by which the transit of the fœtus, through the brim, is facilitated. The ilium is more expanded, and its venter deeper in the female than in the male, to afford greater space and protection to the intestinal viscera and to the gravid uterus; at the brim, the male pelvis is round, or triangular, and contracted, and its cavity deep; while, in the female, the brim is very capacious, of an oval shape, and the basin shallow; this greater capacity of the brim enables the head to pass through with more expedition, while it also presses less injuriously upon the circumjacent parts. The greater shallowness of the pelvic cavity in the female diminishes the surface exposed to pressure during the passage of the head, and mitigates her sufferings; in confirmation of which we find, that tall females, in whom the pelvis is generally deep, and the surface exposed to pressure consequently of greater extent, suffer more than women of moderate stature, in whom the pelvis is usually shallow.

“The symphysis pubis is deeper and the pubic arch more contracted in the male than in the female; a capacious arch is a favourable circumstance for child-bearing, for when the head is in the cavity of the pelvis, a portion of it emerges through the arch of the pubes, which relieves the parts in the interior in some degree from pressure.

“In the female the concavity of the sacrum is greater than that in the male, which enlarges the cavity of the pelvis, and relieves its linings from pressure during the retention of the head, the outlet in the male is very contracted, in the female its capacity is much greater, and it has this increased by the mobility of her coccyx, all of which contribute to facilitate the passage of the fœtus. In the pelvis of a young female, under the age of puberty, we observe that the shape of the brim is round, or triangular, that its largest diameter is from sacrum to pubes, and its shortest from one os innominatum to the other; the diameters of the outlet are also reversed, for its long occupies the space between one tuber ischii and the other, and its short diameter that from the extremity of the symphysis pubis to the point of the coccyx. These peculiarities of a young pelvis continue until the individual commences to exhibit the first demonstrations of having arrived at maturity, when the short begin to lengthen progressively at the expence of the long diameters. Similar changes have been remarked to take place among the lower animals, particularly large quadrupeds*.”

The only diameters with which it is necessary you should be acquainted are the transverse, oblique, and antero-posterior or conjugate diameter; and as they vary considerably at the brim, cavity, and outlet of the pelvis, I must give you their dimensions at each. At the brim *the transverse diameter* measures

five inches, the *oblique diameter* four inches and a half, and the *antero-posterior* four inches; they vary a line or two more or less, but the whole numbers, which I have now given, are quite near enough for all practical purposes; the oblique diameter is *right* or *left*, according to the sacro-iliac spondylosis from which it is drawn; in the cavity of the pelvis the transverse diameter measures four inches, the antero-posterior also four inches, but the oblique diameter remains as before, four inches and a half; at the outlet, the transverse diameter, from one tuber ischii to the other, is four inches, the antero-posterior is now only three inches and a half, viz. from the point of the coccyx to the inferior margin of the symphysis pubis, but, from the mobility of this bone, it is capable of yielding a whole inch, thus making the antero-posterior diameter, at the moment of labour, four inches and a half; the oblique diameter of the inferior aperture, or outlet, as in the cavity, and at the brim of the pelvis, measures four inches and a half. Although the transverse is the longest in the skeleton pelvis, yet, in the natural state, when the bones are covered with their muscles, &c., the relative length of the transverse and oblique diameters is considerably changed, and this, as Levret has well observed, is still more the case during labour: the psœæ and iliacus internus muscles swell during the pains of the fourth stage, and thus occupy a greater part of the pelvis laterally, and reduce the longest diameter of the brim so much that it now becomes the shortest. Hence, gentlemen, we have to hold in mind three chief diameters during labour, of which the longest crosses the pelvis obliquely on both sides, the smaller one goes from one side to the other, and the one of medium length runs from before backwards, crossing this last at right angles; the length of the two last is liable to vary, but that of the oblique diameter seldom does. So much for the dimensions of the pelvis,—on a former occasion I mentioned to you the chief dimensions of the fetal head. But little attention was paid to the mechanism of parturition until the latter part of the last century, and from this reason the most vague and gratuitous opinions were entertained respecting the manner in which the presenting part of the child enters and passes through the pelvis and external passages. Because the head usually passes under the pubic arch with the occiput forwards, it was supposed that this was also the position which it took at the beginning of labour, viz. with the long diameter parallel to the antero-posterior one of the pelvis; this was the opinion of Mauriceau, La Motte, Levret, Stein, &c., a proof how difficult it is to ascertain the truth when such men as these were induced to form opinions so erroneous.

The first, who ventured to deviate from the beaten track, was Fielding Ould, afterwards Sir F. Ould, Physician to the Lying-In Hospital at Dublin. In his Treatise on Midwifery, which was published in 1742, he considered

* Campbell's System.

that, at the beginning of labour, the head is directed with its long diameter parallel to the transverse diameter of the pelvis. Smellie, who published his admirable work on Midwifery, ten years after the appearance of Ould's Treatise, viz. in 1752, maintained the same opinion. Ould thought that the body of the child, at the commencement of labour, took the same direction as the head did, that is with the back directed forwards, the transverse diameter of the chest corresponding to the transverse diameter of the pelvis, so that the child's head in fact was turned towards the right shoulder; this, however, was mere theory, and in this respect Smellie differed from him, for he considered that, until the body itself had entered the pelvis, it had its transverse diameter corresponding, or parallel, to the antero-posterior one of the pelvis.

In 1770, Deleurye published his *Traité des Accouchemens*, wherein he agreed completely with Smellie, and this was the first change which took place in France respecting the mechanism of labour since the time of Mauriceau.

In the following year, viz. 1771, an inaugural dissertation, entitled "De diverso Partu ob Diversam Capitis ad Pelvim Relationem mutuum," was published by Matthias Saxtorph at Copenhagen, and at the same time a similar dissertation appeared at Paris, by Solayres de Renhac, Professor of Medicine at Montpellier, on his being admitted into the Royal College of Surgery, entitled "De Partu Viribus maternis absoluto;" the author died immediately after the publication of it, before he was able to defend it. Baudelocque, who was the pupil of Solayres, has translated and inserted the chief of it into that part of his great work on Midwifery, which treats of this subject; this circumstance he has candidly mentioned, and has taken the opportunity to speak very highly of his former teacher.

Saxtorph and Solayres de Renhac were the first who described the mechanism of labour correctly, viz. that *the sagittal suture (in the most common position) was parallel to the right oblique diameter of the pelvis, the posterior fontanelle directed forwards to the left*, and it is not a little remarkable, that two such valuable and original dissertations should have appeared at the same time, and in all probability without the authors being aware of each other's existence. Plenck has translated Saxtorph's Dissertation into his *Elementa Artis Obstetriciæ*, but without owning from whence he had taken it. Since this period, all the manuals, compendia, systems, outlines, &c. of midwifery, which have been published in such liberal profusion, have been copied more or less from Baudelocque's great work, wherever they treat of the mechanism of parturition,—thus Osiander, Siebold, Jorg, &c. in Germany; Duges, Maygrier, &c. in France; Burns, Dewees, &c.

As it is necessary for you to be acquainted with the various positions in which the head

is said to enter the pelvis at the beginning of labour, according to the different works on midwifery, I shall enumerate *them* first, and, having given you a short account of the presentations of the child, as they appear in books, I shall enter more fully into the description of those few which occur in nature.

The first position of the head, which is allowed by all to occur more frequently than any other, is where the sagittal suture is parallel to the right oblique diameter of the pelvis, the posterior fontanelle being turned forwards, and to the left.

The second position, in which the sagittal suture corresponds to the left oblique diameter, the posterior fontanelle being directed forwards and to the right.

The third position, where (as in the first) the sagittal, or long diameter of the head, corresponds to the right oblique diameter of the pelvis, but the anterior fontanelle is forwards and to the left.

The fourth position has the sagittal suture parallel to the left oblique diameter, the anterior fontanelle forwards and to the right.

These are the position of the head, gentlemen, according to the German schools, and they have a great superiority over those of the French and English schools, inasmuch as they are nearer the truth, and far more simple. Baudelocque has made *six* positions of the vertex, viz. four, as I have just described, and two others with the sagittal suture running parallel to the antero-posterior diameter of the pelvis, in the one (his third position) the posterior fontanelle corresponding to the symphysis pubis, in the other (his sixth) to the sacrum; these positions have been properly rejected by the German schools as not occurring in nature.

The proper and correct position of the head was formerly supposed to be where its long diameter was parallel to the antero-posterior diameter of the pelvis. The works of midwifery tell us that the head *must* make a turn as it enters the pelvic cavity, so that its long diameter shall be parallel to the antero-posterior one of the pelvis, with the face turned into the hollow of the sacrum, and that then, on account of the inclined plane, which the sacrum, coccyx, and sacro-sciatic ligaments offer to it, it is compelled to advance with the occiput forwards under the pubic arch.

At the beginning of labour, or a little before this period, the os uteri is situated high up, and backwards. You will feel it, gentlemen, in the upper part of the hollow of the sacrum. If, therefore, as Baudelocque asserted (and indeed as almost every work after him on midwifery has done), the head presents with the vertex, the sagittal suture should be that point of the cranium which is lowest, and which the finger during examination first touches upon. Now this is *not* the case, gentlemen, for, as Smellie first observed, at the beginning of labour, when the os uteri is dilated sufficiently to admit the finger, we feel the sagittal

suture crossing it, dividing it unequally. Now I have already told you that the os uteri at this period corresponds to the upper part of the hollow of the sacrum, the sagittal suture, therefore, must also be turned in this direction, the perpendicular diameter of the head being oblique or parallel to the axis of the brim, or, in other words, to a line drawn from the centre of the brim through the umbilicus. The part which the finger first touches upon, in the first or most common position of the head, is the right parietal protuberance; this is the part which is lowest in the pelvis, and which is pierced in cases of perforation. Therefore *the correct and real position of the head at the beginning of labour, is with the sagittal suture crossing the os uteri, the parietal protuberance situated lowest in the pelvis.* Instead of the posterior fontanelle being always lower than the anterior fontanelle, one is frequently felt as low as the other, and not uncommonly the anterior deeper in the pelvis than the posterior fontanelle.

The head as it enters the pelvic cavity in the first position, does *not* turn with its long diameter into the antero-posterior diameter of the pelvis, and the face into the hollow of the sacrum, it enters and passes through the cavity of the pelvis with the posterior fontanelle corresponding to the left foramen ovale, the sagittal suture (and, therefore, the long diameter of the head) parallel to the right oblique diameter of the pelvis. The head, also, does *not* advance under the pubic arch with the occiput forwards, but *it is the posterior and superior quarter of the right parietal bone which first emerges*; it is the right branch of the lambdoidal suture, which comes out parallel to the left descending ramus of the os pubis. Thus, gentlemen, the mechanism of parturition in the most common position of the head is very simple, much more so than many works on midwifery would make it appear to be. The head enters the superior aperture of the pelvis *obliquely*, passes through its cavity *obliquely*, and emerges from the inferior aperture *obliquely* also.

When there is not much liquor amnii, the os uteri rigid, and the head firmly pressed upon it, or where the waters have been discharged at the beginning of labour, a swelling of the cranial integuments forms exactly on that part of the head which had corresponded to the os uteri, viz. on each side of the sagittal suture, this I need hardly tell you is produced by the obstruction to the circulation in the scalp, from the pressure which the os uteri exerts upon it; as the os uteri dilates, and as the head gradually alters its situation, it disappears in part, and now forms upon the posterior and superior quarter of the right parietal bone, or that portion of the head which first enters the vagina and external opening. Let me ask you, gentlemen, where would this swelling of the scalp be, if the head came into the world with the occiput forwards? The first mentioned swelling is produced by the pressure of

the head against the os uteri, the second, by the pressure of the head against the vagina and os externum,—we have no term for it in English, its Latin denomination is *caput succedaneum*. If the head presented with the sagittal suture in a line with the antero-posterior diameter of the pelvis, it would also be in a line with the os externum, but this is not the case, for it crosses the left labium at an acute angle, nor does the face of the child turn directly towards the right thigh of its mother as the shoulders are passing through the pelvis, but obliquely backwards, and to the right.

According to the works on midwifery, the position of the head, which, after the first, is the most frequent in point of occurrence is the *second*, viz. where the sagittal suture is parallel to the left oblique diameter of the pelvis, the posterior fontanelle corresponding to the right foramen ovale; this, as the late Professor Von Siebold of Berlin remarked, sometimes occurs so frequently, that for two months almost all the labours at the lying-in-hospital to which he was attached, were with the head in this position; in this position the head is said to follow precisely the same course as in the first, the face turns into the hollow of the sacrum, and the occiput thus comes first under the pubic arch.

After the second position of the vertex, according to the works on midwifery, that position which is known as the *third* should be the next in point of frequency, viz. where the sagittal suture is parallel to the right oblique diameter, the posterior fontanelle corresponding to the right sacro iliac synchondrosis, the anterior to the left acetabulum.

We are told that as the head descends through the pelvic cavity, the forehead turns gradually forwards until the sagittal suture corresponds to the antero-posterior diameter of the pelvis, the occiput being in the hollow of the sacrum, but as the forehead is too broad and flat to pass under the pubic arch, it is gradually forced upwards by the continued action of the pains behind the symphysis pubis, whilst the occiput descends, and presses against the perinæum, which it distends immensely, nor does the forehead clear the arch of the pubes until the occiput is born. In this manner the head is said to pass through the pelvis in the third position, and we are told that it is a presentation which requires unusually powerful pains and favourable proportions for its completion.

The fourth position of the vertex is said to differ from the third, merely inasmuch as the sagittal suture corresponds to the left instead of the right pelvic diameter, the forehead has to undergo the same pressure against the pubes, by degrees the occiput is forced down and made to sweep over the distended perinæum in the same manner as in the preceding case. "From an experience of twenty-eight years (says Professor Nægele), I must confess that this by no means agrees with my observations, one author has imagined it, and

the others have copied from him; according to them the third position of the head should be of far less frequent occurrence than the second. I have (says this distinguished accoucheur) observed as many labours as any person in Germany, and from my observations, which for many years I have made with the greatest possible care and attention, the third position, after the first, is by far the most frequent in occurrence of all the head presentations; on the other hand, the second position of the head, which has been supposed to be so frequent, occurs as an original presentation very rarely*. Thus, for example (says he), out of a hundred labours where the head presented, and which I carefully observed from the very first commencement of the pains till their termination, the third position of the vertex occurred twenty-nine times; of thirty-six labours which occurred at the infirmary of this place, from the beginning of the year 1821 till the present time (Feb. 1821), I counted twenty-two with the vertex in the first position, eleven with it in the third, two presentations of the nates, and one of the face. According, however, to the observations which I have hitherto made, the proportion of the third vertex position to the first, with respect to the frequency of their occurrence, is as one to two and a half. During the time that I saw ninety-six cases of the third vertex position, the fourth occurred only twice, and of more than twelve hundred, which I carefully observed and noted with particular accuracy, I do not find a single instance of the head having been originally in the *second* position. From the observations which I have made (says Professor Naegele), I am thoroughly convinced that in cases of the third and fourth position of the head or vertex, in the more advanced state of labour, the occiput is *not* usually turned into the hollow of the sacrum, but that in cases of the third position of the vertex, where the labour has advanced considerably, the posterior fontanelle is turned from the vicinity of the right sacro-iliac synchondrosis to the right foramen ovale, and in the fourth position, from the left sacro-iliac synchondrosis to the left foramen ovale, and in this manner it clears the external passages. That this change of the third position into the second, and of the fourth into the first, requires no peculiarly favourable circumstances, and that these species of labours can be completed under the most usual proportions of the active and passive momenta which relate to the mechanism of childbirth, by the natural means, in the same time, with the same expense of strength, without greater difficulty, &c., than that species of labour where the head takes the first or most common position †." Baudelocque, it is true, owns that in the third or fourth, or what he calls

fourth and fifth, positions of the vertex, the head, instead of coming with the forehead under the pubes, will *sometimes* make a turn, and come out with the occiput forwards; several authors after him have noticed this fact, but it was always looked upon as a very rare occurrence, and deemed an unhopd for termination to a decidedly unfavourable position of the head. It has been said that this change in the position of the head only occurs in cases where it is very small, and the pelvis unusually roomy and large; this is not the case, gentlemen, for I have seen very large heads born in this position without any unusual difficulty, nor does this position occur so rarely as has been stated, for, according to Professor Naegele's experience, it occurs in the proportion of two to five of the first position, and this has been confirmed by the observations of Dr. Stolz, of the Lying-in-Hospital at Strasburg, Dr. Ulsamer, of the Lying-in-Hospital at Würzburg, and by myself, at the General Lying-in-Hospital in this metropolis.

"The manner in which the head," says Professor Naegele, "when in the third vertex position, is directed during labour and moves through the pelvic cavity, is, according to my observations, as follows:—At the beginning of the second period of labour, and in those who have already borne children even earlier, the great fontanelle is felt directed toward the left acetabulum, and the smaller one to the right sacro-iliac synchondrosis, nearly at an equal height, sometimes the one, sometimes the other, being reached with greater facility. As the *right* parietal protuberance in the first position of the head is the most depending part, so in this case it is the *left*. When the point of the finger is brought in contact with the head, in the direction of the central line of the pelvic cavity, it touches the protuberance of this bone. As the head enters and presses through the superior aperture of the pelvis, the anterior fontanelle corresponds always to the left foramen ovale, as the posterior one does in the first position, and as soon as the head has engaged in the cavity of the pelvis, the great fontanelle turns towards the ascending ramus of the left os ischium, and both can be felt at an equal height as to each other. As soon as the head experiences the resistance which the inferior part of the pelvic cavity opposes to it, or, in other words, the oblique surface which is formed by the lower end of the os sacrum, the os coccygis, the ischiatic ligaments, &c., by which it is compelled to move from its position backwards in a direction forward, it turns by degrees with its great diameter into the left oblique diameter of the pelvic cavity; viz.—the posterior fontanelle is directed to the right foramen ovale, and, as the head approaches nearer and nearer to the inferior aperture, it is the posterior and superior quarter of the left parietal bone which is felt in the cavity of the pelvis opposite to the pubic arch, so that when the point of the

* M. S. lectures.

† Mechanism of Parturition.

finger is introduced under and almost perpendicular to the symphysis pubis, it touches nearly the middle of the posterior and superior quarter of the left parietal bone; and this is precisely the part, as the head advances further, which first distends the labia, with which the head first enters the external passage, and the spot upon which the swelling of the integuments forms itself. As in cases of the first position of the head the posterior fontanelle is usually directed to the *left* when the head passes the external passages, so in this case it is mostly directed to the *right*.*

It may reasonably enough be asked why has the third position remained so long misunderstood, and to a degree unknown?—To this I would allege in answer, 1st, the difficulty of forming a correct diagnosis; 2nd, a person in examining per vaginam is always sure to find what his teacher tells him he is to find, and is naturally rather inclined to attribute any deviation which he may have perceived to his own want of accuracy and inexperience in touching; 3rd, the very circumstance of the third position passing into the second is quite enough to give rise to much deception, because an accoucheur, who at the beginning of labour had ascertained that the anterior fontanelle corresponded to the left foramen ovale, would, on finding afterwards that the *posterior* fontanelle corresponded to the *right* foramen ovale, be much inclined to doubt the accuracy of his first examination; 4th, the difficulty of distinguishing the posterior from the anterior fontanelle is very great. On tracing the finger along the sagittal suture, and coming to a fontanelle, where the edges of the bones are riding over each other, we are disposed to consider it the posterior fontanelle. Now this is by no means always the case, because the bones of the coronal suture will frequently do the same: we can only distinguish by being able to decide whether it be three or four sutures which meet together. In the posterior fontanelle, when in the first position, you will feel a suture branching off from the sagittal suture *forwards*, but none *backwards*; whereas, if it be the anterior fontanelle, a suture will be felt running *backwards* also.

"In the former part of my practice," says Professor Naegele, "not knowing that the head made this turn, I always concluded that my examinations in the early part of labour had been incorrect, and was very uneasy that I did not find it all exactly as the books described, and attributed my want of success in ascertaining the position to my own awkwardness. At length, in a private case in which I was much interested, I again felt what I thought was the anterior fontanelle towards the left foramen ovale, and circumstances occurring which rendered it necessary to apply the forceps and terminate the labour, I found that the head had been actually in the position which I imagined I had felt. Since this time

I have in many cases sat by the bed-side during the whole labour with my finger upon the head, and thus come at the truth*."

The *fourth position of the head*, from its rare occurrence, has not been so much observed as the first and third positions, but from the cases which have come under Professor Naegele's notice, and from those which I have myself had the opportunity of observing, it follows precisely the same course as the third position does.

These positions of the head, which we have now been treating of, and which occur most frequently, have been called by the French and English schools *positions of the vertex*, in Germany they are called positions of the occiput, but in this respect the former is nearer the truth: to speak correctly, they should be called *positions of the parietal bone*. Positions of the parietal bone have been described by some authors as being unfavourable, on account of the two fontanelles being frequently found equally low in the pelvis. This is quite a mistaken notion, for I constantly meet with the anterior fontanelle just as low in the pelvic cavity as the posterior one, and yet no difficulty to the progress of labour results; nor do the shoulders enter the superior aperture of the pelvis in the transverse diameter, and, as they advance lower, turn into the antero-posterior diameter of the cavity and outlet. As with the head, so with the shoulders, gentlemen; they enter the superior aperture obliquely, pass through the cavity of the pelvis obliquely, and emerge from the inferior aperture obliquely also.

At my next lecture I shall describe the presentations of the face and nates.

Reviews.

The Principles of Physiology applied to the Preservation of Health and to the Improvement of Physical and Mental Education. By ANDREW COMBE, M.D. pp. 404. Maclachlan. 1835. Third edition, revised and enlarged.

DR. COMBE is so eminently distinguished as an erudite philosopher and an accomplished author, that no encomiums of ours could enhance his reputation or assist in perpetuating his fame. The present work has passed to the third edition within the space of twelve months, a circumstance amply sufficient to stamp its character and its worth. That we may do justice to it, it will be necessary for us, in the first place, to refer, in a general manner, to its contents, to point out especially the more important subjects upon which it treats, and, secondly, to give such extracts as those of our readers who may not have seen the original may be enabled to form an estimate of its value and importance.

* Mechanism of Parturition.

* MS. Lectures.

The great subject which it is the object of the author to treat, is one of vital moment, one which involves the best interests of humanity, which teaches man the nature of his physical and mental conditions, and tells him of the agents which surround him, both those which are essential to his well-being and his existence, and those which may be inimical to his health or destructive to his life.

We have had numberless writers on the art of preserving health and of prolonging life, from Aristotle down to Sir John Sinclair's "Code;" rules have been laid down which to break would be death. Men are not the same everywhere; the Esquimaux infant, that would lie in the canoe and feast upon blubber does that which would be almost inevitably destructive to an European infant. We are creatures of circumstance and habit; we revel in the luxuries of the earth, and we suffer from the effects of gluttony. If asked—what is the cause of the chief ailments to which flesh is heir? we answer, *instantly*, errors in diet. What is the primeval cause?—*civilisation!*—as civilisation progresses our diseases multiply in number and augment in intensity. The savage of North America, if we credit the records of travellers, is subject to but few diseases; he does not sicken from disorders of the liver, or waste away from phthisis; his life is one of almost incessant activity; he hunts the forests for wild animals to support him during summer, and he pickles the denizens of the ocean for his winter fare. The pampered citizen of Europe feeds his stomach with the products of his native land commixed with the spices of the Indies; he takes turtle-soup and roast-beef in the evening and a black draught in the morning; his life is, like his stomach, one incessant toil and anxiety. But, to leave this region of metaphysics, let us come to a more useful topic,—the author's work.

In his preface the author propounds his reasons for publishing the work; he believes that if the public were aware of the simple yet fine machinery of which our bodies are composed, they would be more capable of discriminating when medical advice is needed, and be better able to avert its aggression, by those simple rules which are laid down for us by nature. "A little knowledge is a dangerous thing," so saug the poet; it may be so in poetry, but we affirm it is not so in medicine. If the chief study of mankind be man, what subject more obviously claims his attention than his physical constitution, its nature and secret workings, the springs that bend and the wheels that revolve, in sweet harmony, in health, in discord, in disease?

The author condemns the practice of non-medical people prescribing for their own complaints, or even for those of others, but strongly urges the public to obtain some knowledge of medicine.

In the first chapter are discussed the subjects of the physiology of animals and vegetables, the distinction between organic and inorganic bodies, objects and utility of physiology, its application, evil results of ignorance on this topic, "what health is, and how to be preserved." The distinction between organised and inorganised bodies has never been clearly drawn; the attempt has often been made, but the last link has always been imperfect, they run, like the animal into the vegetable kingdom, imperceptibly into each other: the author employs only the old arguments to establish the line of demarcation. On the injurious effects accruing to individuals from their ignorance of the relations which subsist between themselves and surrounding bodies, many marked illustrations are adduced. He relates a case of two seamen, who had slept on board one night in harbour, and from closing the skylights too closely the ingress of air into the cabin was prevented, so that in the morning they were both found "almost dead through suffocation," having, he supposes, exhausted the whole of the oxygen of the atmosphere contained in the room. This circumstance, it is fairly presumed, might and would have been prevented, had the sailors known something of the nature of respiration, of the composition of the atmosphere, and its relation to the lungs and the system. An example is given, showing a similar effect of ignorance of physiology. "It is well understood among professional men, that in speaking, singing, and playing upon wind instruments, the lungs are called into play as powerfully as in running, or any other species of severe muscular exercise. From not adverting to this fact, a strongly constituted individual, who brought on spitting of blood by bodily labour, to which he had not been accustomed, conceived himself perfectly safe and even cautious, when he gave up the spade, and confined himself to talking a great deal, which he did daily to numerous visitors, in explanation of favourite views then occupying all his thoughts. The consequence was, that the prescribed treatment was without effect, and a fatal illness was brought on. When the action of the lungs was subsequently explained to this individual, he saw at once the error into which he had fallen." On the subject of idiosyncrasy, some judicious reflections appear. On the opinions of the people of the utility of *this* article of diet or clothing, or the injurious tendency of *that*. For example, "one person will affirm, with perfect sincerity, that flannel is pernicious, because it irritates the skin, and uniformly causes an eruption over the whole body, and that linen or cotton is an excellent article of dress, because it produces no such consequences," and so forth. The vulgar believe that what is (to use an old adage) "food for a goose is food for a gander," that because flannel agrees with me, it must therefore be useful to you; the circumstance requires no

more than a simple notice to establish its fallacy.

The anatomy and physiology of the skin are next brought under discussion, in which are shown its bearings on health. He concludes that the skin performs some important functions, that of expelling from the system some of its effete materials, and that it is a regulator of the animal temperature, and also that effluvia may pass through it by absorption. He notices, fully and accurately, the connexion between the skin and other secretory organs of the body, that, if the skin's function becomes disturbed, other parts of the body may suddenly become deranged. On warm clothing are the following apposite remarks:—

“The advantages of flannel, as a preservative from disease in warm as well as in cold climates, are now so well understood, that in the army and navy its use is cogently and with great propriety insisted on. Sir George Ballingal, in his valuable Lectures on Military Surgery, p. 92, has some very judicious remarks on the influence of warm clothing in preserving the health of soldiers; and, after adducing the testimony of Sir James Macgrigor to show that in the peninsula the best clothed regiments were generally the most healthy, Sir George adds, that, when in India, he had himself a striking proof of the utility of flannel in checking the progress of a most aggravated form of dysentery in the second battalion of the Royals. Captain Murray, also, late of H.M.S. Valorous, told me he was so strongly impressed from former experience with a sense of the efficacy of the protection afforded by the constant use of flannel next the skin, that when, on his arrival in England, in December 1823, after two years' service amid the icebergs on the coast of Labrador, the ship was ordered to sail immediately for the West Indies, he ordered the purser to draw two extra flannel shirts and pairs of drawers for each man, and instituted a regular daily inspection to see that they were worn. These precautions were followed by the happiest results. He proceeded to his station with a crew of 150 men, visited almost every island in the West Indies, and many of the ports in the Gulf of Mexico; and, notwithstanding the sudden transition from extreme climates, returned to England without the loss of a single man, or having any sick on board on his arrival. It would be going too far to ascribe this excellent state of health solely to the use of flannel, but there can be little doubt that the latter was an important element in Captain Murray's success. Far, however, from trusting to it alone, Captain Murray was as careful in guarding against other sources of disease, as against variations in temperature; and with this view every precaution was at the same time used, by lighting stoves between decks, and scrubbing with hot sand, to ensure the most thorough dryness, and proper means were put in practice to promote cheerfulness among the men. When in com-

mand of the Recruit gun-brig, which lay about nine weeks at Vera Cruz, the same means preserved the health of his crew, when the other ships of war anchored around him lost from twenty to fifty men each.

“That the superior health enjoyed by the crew of the Valorous was attributable chiefly to the means employed by their humane and intelligent commander, is shown by the analogy of the Recruit; for, although constant communication was kept up between the latter and the other ships in which sickness prevailed, and all were exposed to the same external causes of disease, yet no case of sickness occurred on board the Recruit. Facts like these are truly instructive, by proving how far man possesses the power of protecting himself from injury, when he has received the necessary instruction, and chooses to adapt his conduct to his situation.”

The next chapter is on the “Nature of Muscular Action,” its conditions during action and when in a state of repose. The evils attendant upon long-continued and frequent action of any series of muscles are eloquently unfolded. We know that it is the character of a voluntary muscle to act in obedience to the will; we also know that the continuance of any individual contraction is exceedingly limited; the familiar illustration well exemplifies it:—one man wagers another that he cannot hold a poker in his hand with the arm extended horizontally for ten minutes; the wager is accepted; with energy the champion enters the arena, but after four or five minutes the deltoïd aches, soon he feels a diminished power, and ultimately he is obliged to desist from the experiment. In the case of a young lady sitting to the drawing table, she leans to the left side, the spinal muscles on the opposite side become put upon the stretch, nay, they are truly in a state of permanent contraction for the purpose of sustaining the body; they are retained in this strained position for an hour or more, until they become fatigued and painful, so that, after the lesson is over, and the body restored to its perpendicular state, there is a tendency to bend to the opposite side. This same unnatural condition takes place two or three times a week, or perhaps daily. The muscles on the left side become permanently shortened, and, as the inevitable consequence, curve the spine to the right side—make the convexity in that direction.

The author alludes to the injuries tight stays inflict upon the delicate young girl at school, by interrupting the free play of the muscles. “Girls thus restrained daily for many successive hours invariably suffer, being deprived of the sports and exercise after school hours which strengthen the muscles of boys, and enable them to withstand the oppression. The muscles being thus enfeebled, the girls either lean over insensibly to one side, and thus contract curvature of the spine, or, their weakness being perceived, they are forthwith cased in stiffer and stronger stays, that support being

sought for in steel and whalebone which Nature intended they should obtain from the bones and muscles of their own bodies. The natural consequences of this treatment are, debility of the body, curvature of the spine, impaired digestion, and, from the diminished tone of all the animal and vital functions, general ill health; and yet, while we thus set Nature and her laws at defiance, we presume to express surprise at the prevalence of female deformity and disease!" These are some but not all the banes of boarding schools. Dr. Forbes states that he visited a boarding school in which there were forty girls, that there was not one girl who had been at the school two years who "*was not more or less crooked!*" This does absurd custom make monsters of the fairest of the human species.

We come next to the influence of muscular activity upon the mind, and *vice versa*. The French army, when retreating from Moscow, became depressed in courage and enfeebled in body, and sunk nearly to the earth through exhaustion and cold; but no sooner did the Russian guns sound in their ears, or the gleam of their bayonets flash in their eyes, than new life seemed to pervade them, and they wielded powerfully the arms which, a few moments before, they could scarcely drag along the ground. No sooner, however, was the enemy repulsed, and the nervous stimulus which animated their muscles withdrawn, than their feebleness returned."

Full exercise for the young is strongly recommended, and few will doubt the justness of the recommendation. Games of every active kind,—shuttlecock and battledore for the young. "Some love the manly toils, the tennis some, and some the graceful dance." With all kinds of playful exercise, that it may be beneficial, must be joined with amusement,—society is the very bond of happiness. "The toil you hate fatigues you soon, and scarce improves your limbs." Dumb-bells, gymnastic exercises, riding, reading aloud, and recitation are all, in moderation, good species of exercise.

On the enlisting of soldiers for the army we notice interesting observations, worthy the attention of the legislature. Very young men, say under twenty, who have not arrived at the age of maturity, cannot bear long marches. Napoleon, after the battle of Leipsic, claimed of the senate a re-inforcement to his army, and so well aware was he of the insufficiency of young men, that he said, "I demand a levy of 300,000 men, but I must have grown men, boys serve only to encumber the hospitals and road-sides." Regular exercise is one of the best means of acquiring strength. In the Memoirs of Marshal Ney we find some remarks on this subject so apposite, that we are tempted to extract them:—

"One of the greatest difficulties in war is to accustom the soldier to the fatigues of marching. The other powers of Europe will attain, with difficulty in this respect, the degree of perfection which the French soldier possesses.

His sobriety and physical constitution are the real causes of the marked superiority he has acquired over the Austrians in that particular.

"Rapidity of march, or rather an able combination of marches, almost invariably determines the fate of war. Colonels of infantry, therefore, should be indefatigable in their endeavours to train their soldiers progressively to ordinary and forced marches. To attain that object, so essential in war, it is indispensable to oblige the soldier to carry his knapsack on his back from the outset of the campaign, in order to accustom him to the fatigues which in the course of it he must undergo. The health of the soldier depends on this being habitual; the men are economised by it; the continual loss, by partial and frequently useless combats, is avoided, as well as the considerable expenses of hospitals to government."—II. 410, 411.

We travel through the chapter on the skeleton to the next, which is on the lungs, influence of impure air inhaled by the lungs on the animal system, ventilating of buildings, exercise of the lungs in health and disease, *cum multis aliis*. We perfectly coincide with the following observations:—"Judicious exercise of the lungs is one of the most efficacious means which we can employ for promoting their development, and warding off their diseases. In this respect, the organs of respiration closely resemble the muscles and all other organised parts. They are made to be used, and if they are left in habitual inactivity, their strength and health are unavoidably impaired, while, if their exercise be ill-timed, or excessive, disease will as certainly follow." Dr. Combe recommends singing, speaking aloud, and crying,—the latter species of exercise in children seldom requires to be enforced. In young people, who have a tendency to phthisis, and have narrow chests, he suggests "rowing a boat, fencing, quoits, &c." In all such cases, however, it must be observed, that there shall be no active pulmonary disease, if so, the remedy would be worse than the disease.

We now arrive at the eighth chapter, which treats of the nervous system; here the Doctor is in his own element,—phrenology is made to bear most effectively on the great machinery of life. The connexion between the mind and the brain, and the reciprocal influence they exert upon each other in health and disorder, give rise to many useful reflections. The Doctor endeavours to show that if the brain becomes excited by the ingress of an inordinate quantity of blood, the mind becomes proportionately exalted in its manifestations; and that if the mind be excited the vessels of the brain take on an increased action, and the face flushes, and the temples throb, and the eyes sparkle.

The author conceives hypochondriasm, and those ill-defined and intelligible maladies, 'yclept "*nervous diseases*," to be frequently the effect of a want of exercise of the mind; "let the situation of such persons be changed

(he says), bring them, for instance, from the listlessness of retirement to the business and bustle of a town, give them a variety of imperative employments, and place them in society, so as to supply to their cerebral organs that extent of exercise, which gives them health and vivacity of action; and, in a few months, the change produced will be striking." Such an alteration the Doctor attributes to changes in the brain. We attribute them to the mind, the soul becomes roused prior to the cerebral excitement. He notices over-excitement, over-action of the brain, as inducing disease and premature death. "Whitbread, Romilly, Castlereagh, Canning," and he might have added Byron, Shelley, and a host of others, goaded on by ambition, impelled to almost unremitting action, which the fragile frame could not sustain.

Early tuition of children, and long school hours are warmly and very properly deprecated. The body is sacrificed to mental cultivation. At page 289 are the following remarks:

"At any time of life excessive and continued mental exertion is hurtful; but, in infancy and in early youth, when the structure of the brain is still immature and delicate, permanent mischief is more easily inflicted by injudicious treatment than at any subsequent period; and, in this respect, the analogy is complete between the brain and other parts of the body, as we have already seen exemplified in the injurious effects of premature exercise of the bones and muscles. Scrofulous and ricketty children are the most usual sufferers in this way. They are generally remarkable for large heads, great precocity of understanding, and small delicate bodies. But, in such instances, the great size of the brain and the acuteness of the mind are the results of morbid growth, and, even with the best management, the child passes the first years of its life constantly on the brink of active disease. Instead, however, of trying to repress its activity, the fond parents, misled by the early promise of genius, too often excite it still farther by the unceasing and never failing stimulus of praise and emulation; and, finding its progress for a time equal to their warmest wishes, they look forward with ecstasy to the day when its talents will break forth, and shed a lustre on its name. But in exact proportion as the picture becomes brighter to their fancy, the probability of its being realised becomes less; as the brain, worn out by premature exertion, either becomes diseased or loses its tone, leaving the mental powers slow and depressed for the remainder of life. The expected prodigy is thus ultimately and easily outstripped, in the social race, by many whose apparently dull outset promised him an easy victory.

"Taking for our guide the necessities of the constitution, it will be obvious, that the modes of treatment, commonly resorted to, ought to be reversed, and that, instead of straining to the uttermost the already irritable powers of

the precocious child, and leaving his dull competitor to ripen at leisure, a systematic attempt ought to be made, from early infancy, to rouse to action the languid faculties of the latter, while no pains ought to be spared to moderate and give tone to the activity of the former. Instead of this, however, the prematurely intelligent child is generally sent to school, and tasked with lessons at an unusually early age, while the healthy but more backward boy, who requires to be stimulated, is kept at home in idleness, perhaps for two or three years longer, merely on account of his backwardness. A double error is here committed, and the consequence to the clever boy is frequently the permanent loss both of his health and of his envied superiority of intellect."

We have given but a few extracts, yet amply sufficient to represent the character of Dr. Combe's work. The spirit of philosophy and philanthropy that breathe through its pages, with the multitude of useful maxims it comprises, urge us strongly to recommend its study to the public at large, and its careful perusal to the profession. It is assuredly one of the most valuable productions of the present day.

The Nature of Cholera. By JOHN G. FRENCH, M.R.C.S., &c. Pamphlet. Livingston. 1835.

The author of the present pamphlet wrote it, no doubt, at the request of some practical friends, and to them he will, no doubt, present it, for we assure him no one who wishes to study the nature of cholera, or to explore further its hidden and mysterious recesses, or to acquire a more efficient mode for its treatment, would be a whit the wiser after the perusal of Mr. French's production. It is true, it contains a few excellent truisms, but they are few in number, and have been much better told before. We do not wish to check the *amor scribendi*, for to write on any subject however trite it may be, and however feeble the efforts, it yet gives a spur to the mind of youth. It teaches him to learn the art of arranging his ideas on any given question in a more methodical manner, and of thinking more correctly. Mr. French's next pamphlet will, we have no doubt, evince an improvement.

"My aim," he states, "in the following pages is to prove that the disease essentially consists in paralysis of the heart; and to show that the consequent symptoms constitute the means by which nature attempts to remedy the evil, analogous to the remedial means she employs in repairing any mechanical injury to the animal frame." The first position he does not prove either by fact or analogy, and the second is so enveloped in obscure phraseology as not to be intelligible. As nature relieves the system by discharges, so the physician should do so likewise, bleed, &c. So they have, but the patients *would die*, Mr. French.

ADVOCACY OF THE SEDATIVE PLAN
OF TREATMENT IN PUERPERAL
CONVULSIONS, AND OBJECTIONS TO
THE INTERMEDIATE TREATMENT.

BY J. H. HORNE, ESQ., M.R.C.S.

To the Editors of the London Medical and
Surgical Journal.

GENTLEMEN,—Among the numerous varieties of diseases which we find come within the powerful, but sanative, influence of opium, when administered as a sedative, we may safely class *puerperal convulsions*; the first symptoms of which not unfrequently manifest themselves prior to the completion of the process of parturition, as in the interesting, and, I may add, instructive, case related by Dr. Cammack in No. 160 of your spirited Journal. To the gentleman who conducted the labour it may perhaps seem unaccountable why the poor woman had symptoms of convulsions ("her screams were violent, finishing with an agitated giggle,") prior to delivery, at the time of delivery disappear, and shortly after delivery reappear. This arose from the sudden, but not lasting, depressing effects of parturition, which, had Mr. Foote taken advantage of by bleeding, as soon as the disturbance commenced, the labour would have been expedited, and probably a return would not have occurred, and the good effects usually produced by the bleeding been followed by the exhibition of a sedative as soon as the child and placenta were expelled.

Dr. Cammack's treatment, I believe, will be considered more verging on the stimulant than the sedative plan, or a mixture of both. Bleeding produces sedative effects, but, if followed by the exhibition of stimuli, they are speedily overcome, and thus, by the alternating or intermediate treatment that has been pursued for ages, the patient not unfrequently perishes. Cases of puerperal convulsions are so common in this metropolis, especially among the poorer classes, that frequent opportunities present for trying the efficacy of any particular treatment that may be offered. For my own part, I am perfectly convinced, from ample cases, that, if the sedative treatment be strictly adhered to, it will prove more successful than any other that has hitherto been recommended. I do not wish it to be conceived that I arrogate to myself as being the first promulgator of this successful treatment, but still that I am ignorant who fairly claims it I must confess. From the very apposite remarks that have been made to me, since I attempted to direct the attention of the Profession to the subject, I am surprised to find that many confine the action of a sedative to the sedative principle of opium alone, and consider that if any other means be used (to induce sedative qualities), it can no longer be considered as sedative. If they mean (but certainly they do not express them-

selves as such) that opium is the best sedative we possess, I agree with them; but there are certain diseased conditions of the system which must first be corrected, or otherwise they will baffle our efforts to produce the desired state, even with opium. The combination of sedatives which I use are bleeding, the application of cold, opium, and digitalis; and when fully induced, I believe I may add that opium will most satisfactorily be found to keep the system in that condition without producing any ill effects longer than any other sedative we possess.

I am, Gentlemen,
Your obedient servant,
J. H. HORNE, Surgeon.

REMARKS ON DR. ELLIS'S STATE-
MENTS ON INSANITY.

To the Editors of the London Medical and
Surgical Journal.

GENTLEMEN,—In your Journal of the 14th inst., Dr. Hay Graham, in his lecture on Insanity, states, that on a recent visit he made to Hanwell Pauper Lunatic Asylum, he was told by Dr. Ellis, the director of it, that "every case of insanity, whatever might be its cause, whether moral or physical, is attended with inflammation of the white (or misnamed *medullary*) substance of the brain!"

As inflammation of this substance has been hitherto considered a rare occurrence by the most eminent anatomists who have made the pathology of insanity the subject of their researches, I cannot yield my conviction without further evidence to this opinion of Dr. Ellis.

Numerous pathologists have declared that they could not discover even a trace of alteration in the brain or its membrane upon the most careful *post mortem* examination of the corpses of lunatics. I have myself been present at similar dissections, conducted by the most experienced demonstrators of our medical school, and with the same result. In the dissection of a female lunatic (a case selected on account of the extreme fury and violence) by Dr. Esquirol, that able pathologist could not detect the slightest mark of disease or change*. Nor is this quoted as a singular result. I therefore cannot help suspecting some error in, or misconception of, Dr. Ellis's remarks to Dr. Graham.

Entertaining a very different view of the condition of the brain of persons insane, and believing that the opinion, that inflammation of its substance is in all cases a concomitant, is likely to lead to dangerous consequences in the medical treatment of insanity, I must be permitted to advise great caution till the doubt be cleared up.

* See Commentaries on Insanity, Part I. on the *Physical Causes*.

Dr. Graham says, also, that "Dr. Ellis has the merit of being the first who combined the moral with the physical treatment for diseases of the mind." Here the mistake is probably the learned lecturer's own; for I have that respect for Dr. Ellis which induces me to think he would never claim a merit to which he is not fully entitled.

Dr. Pinel was the philanthropist to whom the laudable distinction is due, of being the first who recommended the moral means of treating insane persons. The Society of Friends applied this principle as early as the year 1796, when they opened the Retreat at York. It has been acted upon, as far as the means admitted, in that excellent Institution, the Glasgow Asylum, since 1814; and in many other establishments for the insane, both public and private, for many years.

Dr. Ellis will not, I hope, imagine that I intend to disparage his tried and well-known high qualifications for the situation he holds—they are unquestionable. I had an opportunity of witnessing his excellent arrangements and management while he was Director of the County Pauper Lunatic Asylum at Wakefield, and I have embraced every opportunity of adding my humble testimony to his merit.

I am, Gentlemen,

Your obedient servant,

GEO. MANN BURROWS.

59, Gower-street, Feb. 21, 1835.

MR. DERMOTT'S REPLY TO REMARKS
ON HIS "LONDON ANATOMIST."

To the Editors of the *London Medical and Surgical Journal*.

GENTLEMEN,—In your review of my work, *The London Anatomist*, last week, you state that I am in error, because I describe the periosteum to belong to the class of serous membranes, and that the periosteum is fibrous not serous. From this I beg to dissent.

That serous membranes are cellular membrane condensed, was the opinion of the great Haller, and has been that of many other anatomists. We have periosteum, tendons, and ligaments reunited, and bursæ mucosæ formed (nay, even a synovial capsule too, in a false joint, surrounding the head of a dislocated bone) by a condensation of cellular structure. Are we not justified in saying, then, that they are of one family, i. e. that they are different degrees of condensation of cellular membrane? Are not bursæ mucosæ, and synovial capsules, closely allied in structure to the pleuræ and peritoneum?

If we are permitted to class cellular membrane amongst the serous structures (which I should suppose cannot be refused, inasmuch as it universally secretes serum), surely we may include in the same class the periosteum, which secretes serum from its surface, and

forms the external serous surface of the whole of the recent skeleton. If this does not warrant it to be classed with the serous structures, I know not what does.

The loose, flocculent, external surface of the serous membrane shows the true character of the membrane; and the fact of the smooth internal surface not having been unravelled into fibres, physically proves nothing. It neither proves that serous membranes are fibrous, nor that they are not. The serous membrane may be composed of fibres so intimately cohering, and "so closely interwoven as to constitute a smooth continued surface." That tendons and ligaments are inelastic on the one hand, and serous membranes are highly elastic on the other, is no argument that they do not belong to the same family, because you admit that the inelastic tendons and ligaments are condensed cellular membrane, and cellular membrane is highly elastic.

Our brethren, the French, though they far outstrip us in minute anatomical description, are often uselessly fastidious in their distinctions as well as terms, and which we too eagerly embrace*, whereby a strange confusion in our nomenclature is the effect. Nature, I think, does not seem to sanction the distinction between the terms fibrous structures and serous. The term fibrous structure is at best most indefinite, for it necessarily includes muscles, nerves, bones, cartilage, ligament, tendon, cellular membrane, and, probably, synovial capsules, bursæ mucosæ, pleuræ, and peritoneum.

I remain, Gentlemen,

Your obedient servant,

JOHN G. D. DERMOTT.

Theatre of Anatomy, Gerrard-street.
Feb. 24th.

[Mr. Dermott, in his preface to his *London Anatomist*, claimed a reply to the reviewers. We have afforded him the opportunity. When we recommended him to correct the gross error he had fallen into, in designating the *periosteum* a *serous* structure, we did it for the purpose of obviating an error, a great error which his work contained, and which work, we doubted not, would be a test book for students. Mr. Dermott must admit that a *fibrous* structure is not a *serous*. If he does not, why he wars against the system of *General Anatomy*. The structures are as dissimilar as they are opposite in their uses. Were we examiners at the College, we should reject a pupil who did not properly appreciate the distinction. It is so characteristic that the veriest tyro should be accused of ignorance who was not acquainted with the subject.—Eds.]

* The term *fibro-cartilage* is a striking example of this, inasmuch as cartilage is fibrous and ligament is fibrous; how much better the old term *ligamento-cartilagineous* is descriptive of its nature.

Reports of Societies.

ROYAL COLLEGE OF PHYSICIANS.

Monday February 23rd, 1835.

SIR H. HALFORD in the Chair.

An essay, by Dr. Hope, on apoplexy, palsy, and epilepsy, as concomitant with disease of the heart, was read by the registrar.

The paper was rather short, but practical, and abounded with facts, principally drawn from the records of the Marylebone Infirmary. The attention of the medical profession was first directed to disease of the heart as a cause of apoplexy, by the continental writers, more especially Richerand, Bertin, Andral, and others. Few of the English members of the profession have, as yet, thrown any light on the subject, and the communications which have appeared from them have been published solely in the journals, not collected in any monograph specially devoted to the consideration of this malady. The influence of disease in one organ in producing a disordered, and, finally, a diseased, condition in another, is now, we believe, generally admitted and acted upon. Dr. Hope has, in the present instance, endeavoured to point out another link in the great chain which unites organs either by sympathy or reciprocal reaction, in health or in disease. In better hands than those of the Doctor the task could not have been placed, for he is already well and favourably known as a cardiac pathologist.

As the results of the investigations instituted by Dr. Hope, it may be stated that of forty-two cases of apoplexy, palsy, or epilepsy, which terminated fatally in the wards of the Marylebone Infirmary, between the years 1832 and 1834, thirty were accompanied with cardiac disease; in four the heart was reported to be healthy; and in the eight remaining there was no account in the case books of the condition of that viscus. The greatest mortality occurred between forty and fifty, and between seventy and eighty. In the former period, when cardiac disease was present, which it was in the proportion of nine to ten, the affection was located in the muscular structure, to wit, hypertrophy of the left ventricle, in the latter, the disease of the heart was principally ossification; the proportion of cardiac disease at this period was as ten to eleven.

From these premises, the Doctor concludes that disease of the heart is a frequent concomitant of apoplexy, or of its younger sister, (as he terms it) palsy, principally, however, at the periods already mentioned, that is between forty and fifty, and from seventy to eighty. At the other ages when apoplexy occurs, cardiac disease is much less frequently met with.

The practical deductions to be drawn from

these premises are that the heart should be examined in all cases of determination to the head, inasmuch as the plan of treatment usually advantageously adopted to avert apoplexy, when simple or idiopathic, would prove injurious when the complaint is complicated with either hypertrophy or ossification, and at once cause the fit which it is the object to prevent. Active exercise should be avoided as a matter of course when cardiac disease of this nature is present.

After this paper had been read, another, by Dr. Veitch, on the condition of the earth's surface during the invasion of cholera, was brought forwards. There was little novel in the views of the writer of this essay; he seemed very much inclined to attribute the invasion to an hygrometric state of the atmosphere, produced by exhalation from the surface of the earth, as he remarked that the disease principally showed itself, and in its most malignant form, at the estuaries of rivers, and along their course, and in marshy districts, while the high lands were especially free from its attacks. He stated that during the epidemic at Paris, and even while the disease was at its height, the town of Montmorenci, which is situated on a hill, about eight miles from Paris, and overlooks an extensive champaign country, was free, although the neighbouring villages, with one exception, were infected. The exception was the village d'Enghien, which Dr. Veitch considers was protected by the immense quantity of sulphur which is volatilised from its baths, and which is sufficient to impregnate even the ditches. Coupling this fact with the belief of the soldiery, that employing sulphur externally will guard them against intermittents and rheumatic fever, and of the sepoys, that the external application of gunpowder will protect them from the jungle fever, the Doctor is inclined to consider that sulphur may act as a prophylactic against cholera. Negative facts, however, prove nothing unless very numerous, and tried on a most extensive scale. Dr. Veitch therefore advises that large bodies of men, such as garrison troops, &c., be subjected to the plan, which might be put in force by means of a belt containing powdered sulphur, so that the whole system would be speedily impregnated with it.

When the reading of the paper was concluded, Sir H. Halford called on the gentlemen present to furnish communications for the future conversations. He said that the usual plan of proceeding was to submit the communication to the council for its approval ere it was read at the meeting.

There were some fine specimens of the materia medica, the property of Mr. Battley, on the table.

THE

London Medical and Surgical Journal.*Saturday, February 28, 1835.*

REFORM.—OBSERVATIONS ON A SYSTEM OF FEES FOR GENERAL PRACTITIONERS.

As the Parliament, during the present session of which the medical body expects to receive a system of wholesome laws for their regulation, have met; it interests every member of our profession, who has its well-being at heart, to think deeply of the circumstances in which it is placed, and to ponder on the means of extricating it from the pressure of that mass of abuses under which it now totters.

The Government, aided by the voluminous mass of information collected by their Committee at the call of Mr. Warburton, will, we doubt not, lead the van; but it is not, therefore, less imperative on those among us, who can reflect and act, to watch their proceedings; and, if swayed by the jealousy or love of power of certain of our institutions, which are to undergo the process of reformation, they concede too little, or propose a partial and imperfect amount of amendment, to be prepared to remonstrate against such lukewarm proceedings; or, on the other hand, to encourage, if an efficient plan of Reform, and such as we have a right to expect, is brought forward.

That the subject will afford matter of acrimonious dispute cannot be doubted; the interests of two mighty parties, but one far mightier than the other, will be at issue, and appear in the field of contention; the majority will have the public opinion to back it, the minority is at strife with the integrity and spirit of the age. The abettors and conservators of Gothic warts and ancient abuses, assisted by their

corps of corruption, will labour hard, clause by clause, to keep their well feathered nests untouched, and to render the sum total of grace as near to zero as may be practicable, while the long-duped and much enduring class they have unmercifully plucked will, strong in justice and doubly armed, bring the artillery of their wrongs to bear on the rotten but warm fabric of their oppressors' safeholds. Among the latter there will be unanimity, and the cant of privilege and vested rights will be paraded in awful battalia against the forces of reason and justice, but virtue shall overcome depravity, and we predict, that if no grand division infect and enfeeble the camp of the former, that threadbare arguments and skeleton devices shall be borne away by the vigour and substance of truth, like chaff before the wind, leaving her, as trophies of victory, a well won field and a splendid Reform!

Among the several schemes that jostle each other, entertained by different degrees of medical reformers, there is one on which we proceed now to offer a few comments, leaving others to be observed on in future numbers. The plan we allude to, is that of abolishing the general practitioner, and making two orders only, one of pure physician, the other of pure surgeon. Those who would adopt this plan, desire it because they believe that all professors of the healing art should enjoy equal rank, and this they deem inconsistent with the avocation of a general practitioner as now constituted, seeing that he acts in the triple capacity of physician, surgeon, and accoucheur. Now we think, also, that one medical practitioner should not rank above another, unless in so far as merit may effect such elevation, but we go farther and say, that the sum of professional education being made equal in all medical professors, there can be no

just reason why one, who chooses to practice at the same time both medicine and surgery, and even (although certainly desirable that it should not be so) dispenses his own prescriptions, should not enjoy the same consideration and privileges as the *soi disant* pures. We are the more inclined to adopt this opinion from surveying the position in which the public are placed with respect to their medical advisers, the most numerous and useful of whom are decidedly the general practitioners; by abolishing them at once, if such a thing were practicable, a rude dislocation instead of a gradual softening of long cherished prejudices would be attempted; but such a change could not be suddenly effected in a matter which so nearly concerns, and mingles with, the public feeling; it is true, that legislative enactments upon the every day business of life, although running counter to the prejudices of the many, are tolerated, and this the more willingly as they are more remote from disturbing the economy of every one's personal conduct, but begin to coerce a man on those subjects in which habit has taught him to consider himself paramount and unfettered, and you at once rouse that demon of discord and contradiction within his bosom, which although it might not succeed in the attempt, would, nevertheless, most assuredly dare to resist, if not to overturn, the obnoxious power. Now, in no instance, can a legislature interfere with less prospect of success, than in endeavouring to dictate the mode in which individuals shall manage their personal concerns, so far as respects either the health of their souls or bodies; in the former, conscience, a power greater than man can restrain, guides him; in the latter, although perhaps mere opinion may direct, yet it is an opinion, which he will not easily forego, and which is ever

present and in action; it is one which he has imbibed from his youth upwards, and not so likely to give way to an *ex cathedra* condemnation, as to a gradual and almost imperceptible conviction, arising from witnessing the advantages of a better system than he has heretofore followed.

If there be any truth in what we have just stated, it would seem advisable that the legislature should allow the change (if change be contemplated) in the state of the general practitioners to proceed in a great measure from themselves, that so it might become correspondent with the gradual mutation, which, under intelligent laws to be enacted, would, doubtless, sooner or later, affect the public opinion. One of those laws should enable the general practitioner to recover fees for *medical* attendance, according to a certain scale, formed to meet the exigency of the times; the graduation of such a scale could not be an affair of difficulty, if entrusted to practical and competent judges; and if every medical man were, afterwards, to encourage as much as he could the impression, on the mind of his patients, that fees, on a moderate system, were preferable to charges for medicine, and in every instance where it was practicable, were to substitute fees for the same, the first step in the change from surgeon-apothecary into pure surgeon, or pure physician, would be much accelerated.

That there are few medical practitioners who would not prefer being remunerated by fee to sending once a year or so a lengthy commemoration of pills and potions enough to bring back the illness they were administered to cure, we are fully persuaded, the advantages to themselves being much greater in the one case than in the other; their yearly bills, excepting in a very confined number of first rate practices, being of very uncertain

validity, even to the extent of making their losses equal a third or more of the gross amount of credit, besides the unpleasant feeling produced by squabbles and disputes about the quantity of physic sent, or the enormity of charges. The fee system would abolish these disadvantages and vexations, and, moreover, superadd that respectability to the practitioner which ought, by virtue of his education, to belong to him. Moreover, proceeding with the naked truth upon the point of our pen, we assert, without fear of contradiction, that, to the young practitioner commencing business, the fee system, when once generally established, would be a God-send; for how does the case now stand with him?—If he possess but moderate means (generally the fact) in friends and money, he must, following the routine of others in his profession, open a shop at a considerable pecuniary outlay, stocking it with drugs, &c., almost useless in private practice, but absolutely necessary to “make up a show,” and accommodate such customers as the chemist, grocer, and quack have left him. In this shop must he await with due patience and humility the advent of that practice, to qualify himself for which he has already expended much time and means, and which, in too many instances, never comes, or, when it comes, brings not a co-extensive reward; for, be it known, in spite of the vaunted profits some allege to belong to the sale of medicine, a long list of melancholy contradictions, in the shape of failures from giving long credit and unpaid accounts, prove the contrary. The vending medicine is, in fact, in the majority of cases, a losing speculation to the beginner, who, while feeling his way amid the darkness of uncertain returns for services done, and the gloom of deferred hope, too often falls the victim of

disappointment. This the fee system would ameliorate.

Credit is the soul of general practice as now constituted; without being prepared to grant it the practitioner may as well sheath his scalpel, or (must we use a plebeian phrase?) shut up shop, for patients he will have none; and, if he does grant the hungry boon—this credit—he does so at the risk of its being eternal.

The fee system would, in a great degree, do away with this dead weight upon the incipient struggles of medical men to get into practice; credit to the substantial would no doubt still continue to be given, but the classes which now pay worst and expect most would be obliged to put their hands into their pockets more frequently than they are inclined to do under the present system. Labourers, mechanics, and the smaller middle fry, would soon understand it to be more to their profit to give a small ready money fee for advice, and be left to their own discretion in the matter of furnishing themselves with the necessary medicine when and where they pleased, than to incur an uncertain amount of debt depending upon the skill or conscience of their medical attendant. The poorer and working classes, looking keenly after their interests, would be the first to hail and uphold the plan we now propose, and thereby become the supporters instead of the depressers of the young medical aspirant.

We have said thus much upon the subject of fees, from a conviction that were the general practitioner to adopt, whenever practicable, such a mode of remuneration in preference to furnishing medicine, the trading fungus which now luxuriates in rank growth upon our noble science would quickly die, and, like an unhealthy excrescence, be cast away, and finally delivered into more fitting hands.

It may be said, this is a degree of reform which we have the power of accomplishing ourselves without external aid, but, for some reasons or other which it is needless here to explain, the *vis insita* required for the purpose is wanting among our meritorious brethren, and the impulse must therefore come from without. The government must furnish it; and when, among other mighty efforts at advancing the utility of our country's institutions, it lights upon ours, let us, to use an eastern style of expression, keep the eye of intelligence wide open, and the hands of unity ready to act.

COLLEGE OF PHYSICIANS.

THE College of Physicians is still at work, and anxiously extending its consultations, without allowing a particle of their tendency to leak out of the old sieve they have so adroitly handled since the time of their blustering patron, Henry the Eighth. Can any good be intended where so much secrecy is observed? Will the misers quit their hoard, and propose a degree of reform in their antique house which shall be somewhat more than a shadow—a phantom of darkness? Let them be upon the alert; for assuredly even now the ghost of Thomas Linacre looks out of the cloud that envelopes their camp in Pall Mall and frowns denunciation. Let them look to it, we say, and grant their step-children, the Licentiates, and the medical profession in general, a fair field and enlarged privileges, or what they refuse to concede with a good grace shall be wrested from their gripe by the strong hand of compulsion. This is not the age to breed or foster monopolies, and he who runs may read that their downfall is at hand. Let the learning of the Fellows then for once shake hands with worldly wisdom; their erudition combine with com-

mon sense to meet the coming change, for change there shall be, and that speedily.

To our brother reformers we say, when the tide of success has set in, be not afraid of pursuing steadfastly your measures of reform, and when you have succeeded in one point do not hesitate at the sound of your voices, or recoil when viewing the change you have effected, but tread boldly and fearlessly on till all you require is achieved; and, when the victory is won, follow it up closely; and, instead of relaxing into indolence, thinking it enough that the battle is won, reap its fruits.

Foreign Medicine.

Hydrargyria (Erythema Mercurialis).

Read before the Medical Society of Amiens.

BY M. ALEXANDRE, PROFESSOR AT THE
SECONDARY SCHOOL.

M. RAYER, the author of the article *Hydrargyria*, in the "Dictionary of Practical Medicine and Surgery," says, that in the course of twenty years of study, he has only met with three cases of this disease, although he has treated himself, and seen treated by others, a great number of patients, in whom the use of calomel or blue ointment has caused excessive salivation, and although he had attended a great many gilders affected with mercurial tremors. The frequency of hydrargyria in this country, and some peculiarities attending this case, have induced me to bring it before you.

M. F—, thirty-four years of age, of a strong constitution, subject to palpitation of the heart, and having a slight habitual pulmonary catarrh, called me in on the 12th of July, 1833.

The thighs, scrotum, and lower half of the abdomen, are the seat of a purple uniform redness, without efflorescence; the inside of the thighs is greasy and blackish, giving proof that the mercurial ointment has been rubbed in on those parts. The super-umbilical region of the abdomen, the anterior part of the chest, the neck, the face, and the arms, are covered with numerous red and irregular spots, from six to ten lines in diameter, formed by the agglomeration of little papulæ, of from half a line to a line in diameter, slightly prominent, very full, and not containing any fluid. This redness dis-

appears under the pressure of the finger, but returns very intense when that pressure is removed; the skin is very hot, especially of the thighs, scrotum, and abdomen; the epigastrium painful on pressure; the imbibition of liquids causes an unpleasant sensation of weight at the stomach, and sometimes gives rise to nausea; the tongue is very red, and seems to be thicker than usual; it is covered with a thick grey coat; the whole of the mucous membrane of the mouth and pharynx is very red, but there is not any difficulty in swallowing; thirst; pulse indicates fever; the pulmonary catarrh is increased in severity.

The patient informed me, that being desirous of curing a venereal ulceration, which showed itself about four days ago on the glans penis, a few days after coition, as well as a small bubo in the groin, he had the advice of a chemist, and accordingly had recourse to frictions with mercurial ointment on the inside of the thighs; for the last ten days* he had employed it two, three, and four times a day, using each time a piece of the ointment as big as a large bean, and he further stated, that the skin of the thighs became red after the earliest frictions, but that did not prevent his continuing to use the remedy. He had also taken aperient boluses, without mercury, according to the direction of the chemist, and he had Vigo's plaster with mercury covering the bubo. The skin was washed with soap and water to remove the remains of the blue ointment; the patient's linen was changed, he was ordered to abstain from food, and refreshing drinks were prescribed.

13th. The redness of the integuments of the thighs, the scrotum, and the abdomen, continues as intense as ever; the maculæ of the chest, neck, face, and arms, are increased in size; the eruption has extended to the legs and the scalp; the gastric symptoms and the general phenomena are the same as yesterday; urine muddy, depositing a brick-red sediment.

14th. The maculæ continue to enlarge, the papulæ which form it have united together, and are less prominent, in many parts the redness is uniform, without any intervention of sound skin; in others, between the spots there are portions of skin preserving its whiteness; complains of great debility and depression, with insomnia, and very great general heat.—Continue.

* This case is very badly detailed; there is no attention whatever paid to dates. At first we find mention of *four* days previous to M. Alexandre's visit as the date of the chancre; then we hear of the ointment having been employed for *ten* days, *six* days consequently before the patient had his chancre, so that he was treating himself by anticipation for a disease which at that time he had not. Really members of the medical profession, if they wish the cases they publish to be of use, should be a little more attentive to the *facts* they detail.—Eds.

15th. The redness of the thighs and scrotum is rather less intense; a large portion of the epidermis has detached itself from the inside of the thighs, the skin of the abdomen, from the pubes to above the umbilicus, has returned to its normal condition; with the exception of the arms and legs, where the primitive form, in spots, continues, all the rest of the skin is affected with an uninterrupted redness, of a violet colour at the back, nates, and most depending parts; pressure does not efface the redness on those parts, but it does so on the anterior surface of the body. The heat is much greater, burning, with occasional itching; the gastric symptoms are more marked; pulse rather weak, 116; oppression, agitation, inquietude. Venesection. M. Barbier was now called into consultation. An opiate, containing thirty-six drops of laudanum in a four ounce mixture, was ordered, a spoonful to be taken every two hours.

16th. The integuments of the abdomen have resumed their redness, and the epidermis is separating; the thighs are rather more red, the new cuticle is also being detached, but in small scales; the eruption is losing its primitive form on the arms, legs, face, and scalp, the spots becoming enlarged, and the papulæ effaced; pulse, 100. In the evening the fever increased, with agitation, depression, and insomnia.

From the 16th to the 20th the disease remained much in the same state.

21th. The desquamation has gradually ceased on the thighs and abdomen, and their skin has nearly resumed its natural colour, is softer, and rather moist; the skin becomes redder at night, and the heat is very inconveniently increased, with fever.

26th. The skin of the thorax has become normal; it is white, soft, and free from desquamation; that of the face, scalp, arms, and legs, is still desquamating in small scales; the back of the hands is furrowed with deep, transverse fissures, corresponding with the folds on the back of the phalangeal joints.

28th. The integuments of the fore-arms, hands, legs, feet, and scalp, are dry, and still desquamating; in the other parts of the body it is normal; the eyes are almost well; the pulmonary catarrh has returned to its usual condition; the appetite continues to improve, and digestion is properly performed; the mind is still depressed, and the insomnia persist.—*Journal Hebdomadaire et Gazette des Hôpitaux.*

British Hospital Reports.

ST. GEORGE'S HOSPITAL.

CASE I.—*Strangulated Hernia — operation early.*—Charlotte Kitter, ætat. 34, admitted Feb. 19th, 1834. Catamenia present. Has had femoral hernia for some years, reducible till 10 o'clock, A. M., after which attempts were made to reduce it without success, and in

the evening she was sent to the hospital. There was a femoral hernia of some size, turning over Poupart's ligament, very hard and firm at the ring, and the tumour itself tender and painful. The chief circumstance, Mr. Hawkins said, in his opinion, to be attended to in strangulated hernia, is the state of that part of the protruded bowel or omentum which is *embraced by the sac*, for if that portion is very hard and tender, it is not very likely to be reduced, and the part below may be quite flaccid and unattended with pain, although mortification may be going on; a portion of tightly strangulated bowel being defended by omentum or by a quantity of fluid in the sac below the ring. For this reason Mr. Hawkins thought it right in this case to proceed at once to the operation, without further trials to reduce it, which was done about twelve hours after the strangulation. The sac contained about five inches of intestine, which was dark coloured, but quickly recovered its proper circulation when the stricture was divided, which was very broad and tight. After the bowel was returned, a large quantity of serous fluid came down from the abdomen. She was then left quiet for the night.

20th. An injection was given, and afterwards three doses of Epsom salts and infusion of roses, and the bowels still continuing confined three grains of calomel, followed by some castor oil, were also given. In the evening the bowels had been freely open, and no pain whatever was felt.

22nd. Beef-tea was given, and the next day fish, the patient not having had a single bad symptom. On dressing the wound it was found to have almost united by the first intention. A small portion of skin, however, near the incision, looked as if it was going to slough from the force used in the taxis, which did actually take place. The patient however quickly got well.

CASE II.—*Rupture of Intestine by a Blow upon a Hernia.*—The records of forensic medicine possess more than one such case as the following, and show the danger of leaving a hernia unreduced, and unprotected by a truss, however common such carelessness unfortunately is in all classes of life.

Henry French, æt. 55, admitted Jan. 11th, 1834, under the care of Mr. Hawkins. This man had been leading a horse drawing a cart, when the animal took fright, and ran against some iron railings, by which means he was squeezed between the railings and the wheel. He had slight scalp-wounds in one or two places, and a severe contusion of one arm; but what he chiefly complained of was, severe pain in the abdomen, especially on the right side, where there was an inguinal hernia, that he thinks was down at the time of the injury, and which came down also several times after his admission. There was no great anxiety or collapse when first seen, the pulse was 84, full and soft. Leeches were applied to the

part, and saline and antimonial medicine ordered. The next day he seemed pretty comfortable, and said he was relieved by the leeches, though there was still some tenderness. Leeches repeated, with aperient medicine, as the bowels were not open. Pulse 90 and small. In the evening he felt better, though some distension of the bowels was perceived. Between 12 and 1 o'clock the house surgeon was called up to him, and found him in very great pain over the whole abdomen, with exquisite tenderness on the least pressure; constant retching; much distension of the abdomen; the skin cold, and the pulse hardly perceptible; in short, the most acute peritonitis had evidently come on. He continued much in the same state till about 3, when he aroused himself, and asked for some warm gruel to drink, but before the nurse could procure it he had fallen back and expired, about forty hours after the injury.

On examination the next day, nothing was found in the hernial sac, but in the right iliac fossa a portion of small intestine was seen in a cavity formed by adhesion from recent lymph, and enclosing a quantity of lymph and pus and a little faecal matter. The bowel was slightly ecchymosed, and a small rupture of its coats was seen about one-third of an inch in length. The whole peritoneum was inflamed and coated with lymph.

The hernial sac presented a curious complication, that in an operation might have caused some difficulty. Below the sac was a hydrocele, and behind the sac a large varicocele, and in front of it was a fatty tumour about two inches and a half long, and surrounded by a smooth cyst, in which it lay loose like a portion of omentum in a hernial sac; so much so indeed, that it was thought at first there must have been a double hernia.

CASE III.—*Operation twice performed—Mortification of Bowel—Severe Symptoms by separation of Slough. (?)*—James Wheatley, æt. 46, admitted July 21st, 1831, with strangulated hernia, for which he had worn a truss since he had been operated on by Mr. Hawkins for the same hernia, about a year ago; but he had allowed the rupture to come down occasionally, and it had not gone up again since Monday (three days ago), when, after some exertion, following a hearty meal of potatoes, a large portion of bowel had descended. Vomiting came on two hours afterwards, and had continued till the present time, and hiccup yesterday.

He complains now of violent griping pains in the abdomen, constant retching and vomiting of stercoraceous matter, with occasional hiccup. Abdomen tender around the hernia, and still more in the epigastrium, which is the chief seat of his pain; no motion since Monday; countenance anxious; pulse 76.

He at first refused to have the operation performed, but submitted in the afternoon; after ice had been applied for some time;

Mr. Hawkins performed the operation with some care, in consequence of the former operation, and found the intestine in contact with the fascia, the peritoneal sac having been obliterated in front by the previous incision, so that, in the lower part of the sac the bowel was closely adherent to the common integument. The intestine consisted of about five inches of the smaller bowel; it was of a bright red colour, from inflammation, and thickly coated with recent lymph, and, upon separating the adhesions, a spot, of the size of a shilling, was seen to be quite black, looking like coagulated blood, and without any glossiness, and the coat of the bowel very thin. After a little consideration, Mr. Hawkins returned it into the abdomen, observing that the mortification of so small a portion could often be effected within the abdomen, so that the slough separated into the canal, and a better line was presented than if the surgeon was to open the bowel and leave an artificial anus; and that, if the requisite adhesions did not take place for this object, still it was generally found that the mortified spot remained at the internal ring, and, consequently, that the fæces did not necessarily become extravasated into the abdomen, but could very often come away by the wound. The case demanding great attention, however, about the period when the slough would probably separate.

The vomiting, and hiccup, and pain continued after the operation, and, about four hours afterwards, twenty leeches were applied (fomentations not appearing to give any relief), and the following mixture—

R. Magn. sulph. \mathfrak{z} ss. Acid. sulph. dil. \mathfrak{ij} v. Aq. menth. viridis, \mathfrak{z} ss.—
M. fiat haust. 2dis horis sumend.

26th. 8 A. M.—Tongue more dry; pulse 86, weaker; bowels just opened twice, the evacuations being very dark and fœtid.

One P. M.—All pain and tenderness gone; hiccup continues; pulse very low. Allowed beef-tea and arrow-root in small quantities. Ordered to continue the draught, and in the evening to have an injection of gruel, and to take some pills, with calomel gr. \mathfrak{ij} . and pil. sapon. c. opio, gr. v.

23rd. More comfortable; pulse a little stronger; bowels not at all free.—Cont. haust.

24th. Tongue clean and moist; no pain or tenderness; complains only of hunger, but Mr. Hawkins allowed no solid food.

25th. Wound dressed, and found almost wholly united by the first intention.

27th. Some heat of skin; bowels very little open; complains of griping pain.

Appl. fofus papav. Cont. haust.

29th. (8th day.) Quite comfortable till this morning about one o'clock, when he was attacked suddenly with violent pain and tenderness in the abdomen; constant vomiting, which soon became stercoraceous; tongue

dry; pulse very small and rapid; great flatulence complained of.

An injection was given, which brought away no fæces. His mixture was repeated every two hours, and the abdomen fomented, without relief.

10 A. M.—Symptoms increasing.

Applic. hirud. xxv. abdomini.

1 P. M.—Mr. Hawkins saw him, and found the symptoms not relieved by the leeches. Abdomen quite tympanitic; very anxious.—
V. S. ad \mathfrak{z} xij.

R. Calomel, gr. v. Opii, gr. j.—M. statim.

R. Aq. menth. pip. \mathfrak{z} jss. Sodæ tart. \mathfrak{z} iij. Magn. \mathfrak{z} ss.—M. 2dis horis donec alvus respond.

6 P. M.—Calomel, gr. v.

10 P. M.—Pain lessened considerably; has just had a copious motion; the retching and hiccup continue; pulse small and fluttering; extremities cold; surface of body bathed in cold perspiration.

Applic. empl. Iyttæ magn. abdom.

R. Calomel, gr. iij. Opii, gr. ij. stat.

30th. Has a good deal rallied. The extremities began to get warm soon after the application of the blister; skin now moist and warm; vomiting; pain and tenderness ceased; bowels discharging chiefly secretions without fæces.

Cont. haust. aper. salin.

Rep. pil. vesp.

31st. Rep. pil. et haust.

Aug. 2nd. Has very much improved, but has had several returns of vomiting and pain to a slight extent; bowels not free.

R. Pil. hydrarg. gr. iv. Pil. sapon. cum opio, gr. iij. Extr. coloc. comp. gr. v. M. o. n. s.

R. Ol. ricini, \mathfrak{z} ss. mane sequente.—Beef-tea, &c.

5th. Was again attacked this morning with vomiting and griping, without pain.

R. Calomel gr. iij. P. opii, gr. j.—M. statim.

Enema terebinth.

One P. M.—Vomits stercoraceous matter; tongue dry; hiccup; not much pain.

Rep. pil. cal. et opii, statim et h. s.

Vespere.—Symptoms continue; extremities cold.

Vini albi, \mathfrak{z} ij. Calomel gr. iij c. p. scam. gr. ij. statim.

Olei ricini, \mathfrak{z} ss. mane.

6th. Vomiting continues. Evacuations not fecal for some time; surface still cold.

Vini, \mathfrak{z} iv. Ova.

Empl. Iyttæ abdom., et postea ung. hydrg.

7th. Beginning to rally a little; vomiting continues.—Burnt brandy, \mathfrak{z} iv.

9th. Going on well. Continues his wine and brandy, and allowed also some porter.

13th. Going on well to-day, when some griping returned, with vomiting, and again on

the 20th, at which time the abdomen was very much swollen and tympanitic.

It is unnecessary, however, to detail the rest of the case, as it went on nearly in the same way for some time longer, before he was finally cured, during which time the treatment of the case was nearly the same—supporting the general strength, while the action of the bowels was restored by calomel and opium, and purgatives, &c.

Mr. Hawkins attributed the symptoms to the separation of a slough from the bowel, by which inflammation was produced, with a great deal of irritation and disturbance of the functions of the bowels, from the consequent narrowing of the canal of that part.

WESTMINSTER HOSPITAL.

Cancer.

THERE is, perhaps, scarcely any disease within the domain of surgery so painful and so certainly fatal, if left to itself, as cancer. Palliatives or medicinal treatment prove unavailing, and the knife of the operator is far from being always successful. Its progress is slow, but, unfortunately, too sure.

The predisposing cause of cancer has not yet been ascertained; and it would be an useless waste of time to allude to the different theories which have been brought forward. In some cases it is said to be hereditary. Napoleon Buonaparte is considered to have perished in consequence of an hereditary cancer of the stomach, his father having died of the same complaint at the early age of forty.

Cancer may affect the skin, the mamma in the female, and, occasionally, in the male, the testes, scrotum, uterus and its appendages, rectum, penis, stomach, œsophagus, lips, tongue, and the pharynx; the nose, eye, lachrymal gland, palpebræ, and the bones, with various other structures, have been the seat of scirrhous.

Cancer of the breast generally shows itself by a small, hard, and indolent tumour, which may have existed for some time previous to its discovery, as it causes, in general, no inconvenience or pain to the patient. In this state it is called *occult cancer*, or scirrhous tumour of the mamma. Some accidental cause arises, as, for instance, a blow, or some other injury inflicted on the part, and the tumour is then perceived, because attention is directed to the breasts, and also because the accident, by causing irritation, tends to develop the malady more rapidly, and to bring it into activity. In consequence, a tumour which had been stationary for years, and might have continued so for an equal or greater length of time, is rendered active, or, caused to put on its malignant character, increases rapidly in size, becomes of a stony hardness, and the seat of lancinating pains, darting into all the vicinal parts, and the integuments assume a leaden aspect, and are freely marked with large blue

and tortuous veins (whence its name, *cancer*), and the nipple is retracted. As time advances the disease forms adhesions with the surrounding parts, which, in their turn, become vitiated, long processes of cancerous structure passing deeply into the cellular tissue, taking root as it were. While this is taking place, the patient's health suffers materially, the countenance takes on an anxious appearance, and becomes of that leaden colour which is the general characteristic of malignant disease. Rest is disturbed and finally broken by extremity of pain; the appetite fails, and the bodily powers are evidently giving way under the infliction, and all or many of the functions are performed irregularly. The pain becomes more and more intense; the integuments inflame, thin, and crack in several places, giving passage to a sanious or sanguinolent foetid discharge. The cracks enlarge and unite together, forming an ulcer with rough, jagged, overhanging edges, and irregular elevations and depressions in the cavity itself. This constitutes what is called the *open cancer*.

Other parts of the body become similarly affected, either at the period when the scirrhous ulcerates, or soon after, sometimes even a little antecedent. The chain of glands along the upper and lower margins of the pectoralis major, leading to the axillary knot of absorbents, become enlarged and scirrhous, and finally those in the axilla. The uterus may also, as it is a great sympathiser with the breast and does occasionally participate in the disease, take on the scirrhous structure, and ulcerate, forming of itself one of the most painful maladies to which a female can be subject.

An open cancer is an ulcer of such a peculiar appearance, that it may be, generally speaking, very easily recognised. It is irregular in shape, and also in its general aspect; the edges of the ulceration are rough, ragged, and inverted, hanging over deep hollows and irregularities formed by large, unhealthy, flabby granulations, if such they may be called, situated at varying intervals. The whole surface is plentifully bedewed with a sanguinolent sanies, exhaling a most foetid odour. The pain becomes more and more acute, the ulceration continues to spread, and may even affect the ribs or the sternum beneath. In this condition it seems some women may live for years miserable objects; but whether it were better to die than to exist under such intensity of suffering can hardly be a matter of doubt. The patient, however, most commonly sinks at the end of a few months, exhausted by pain and the other drains on the constitution.

The treatment of cancer divides itself into palliative and operative, for the latter, in by far the majority of cases, does not merit the name of radical.

The palliative is the only plan that can or ought to be adopted in the advanced stage of the disease, when the cancer has ulcerated, or when the axillary or pectoral glands are involved in the change of structure. A very

gloomy prognosis must of necessity be formed in such a case relative to the probable success of an operation; perhaps there is not an instance on record where it proved ultimately successful. The treatment, therefore, would mainly consist in the exhibition of anodynes, &c., so as to alleviate pain, the averting of all causes of irritation, and treating symptoms as they arise. Such a case is undoubtedly without the pale of surgery; but still it is a great advantage to be enabled to disarm the king of terrors, and to lay smooth the passage to the grave.

The latter, or the operative plan, again, may be divided into that in which pressure is employed, or where caustic is used, and that in which recourse is had to the knife, but the general ill success of these methods induced several members of the profession to seek for a medicinal agent which might effect a cure. It is much to be feared that hitherto their efforts have been fruitless. The celebrated Stoerck of Vienna introduced several narcotics into practice, as almost specifics for cancer. He confined his representations of beneficial agency in effecting a cure to the occult stages, considering them, however, as palliative in the more advanced condition of the breast. It may therefore be justly concluded, more especially as his remedies have failed in the hands of others, that Stoerck mistook cases of simple tumour, or enlargement of the mammary gland, for carcinoma. There is nothing improbable in this supposition, for some of the most celebrated and talented surgeons have committed similar errors. Of the narcotics which he employed, the Aconitum Napellus was most used, a remedy which still possesses a very high reputation in Germany. The whole of them enjoyed a high degree of ephemeral fame, but which was soon lost, as it was found that they did not fulfil the high promises of their learned discoverer. It has been alleged, that the cause of failure may be found in the wrong species of plant being used, or to the preparations being carelessly made. Probably the subject is worthy of further investigation. Iodine has of late been recommended, but without advantage.

Another plan, which was some time ago in great vogue, was the employment of pressure. This was the invention or discovery of a surgeon of the name of Young, who was so enthusiastic in its praise, as to found or cause to be founded a cancer dispensary, where he gave his plan a fair and free trial. It consisted in the application of strips of an unirritating plaster over the whole breast, and that as tightly as could be borne. This was continued and re-applied. At the end of a fortnight or three weeks some diminution would be evident: this was more apparent at the end of six weeks or two months, when the patient and the surgeon would be buoyed up with the hope of a speedy and certain cure being effected; but, on a more strict and close examination being instituted, it was found that the pressure had caused the absorp-

tion of every particle of fat in the surrounding cellular tissue, but had left the tumour as it was. Consequently this plan was necessarily abandoned.

Surgeons have always been, and perhaps always will be, much divided as to the origin of cancer; whether it be constitutional or local, a question of considerable importance, as on it depends the propriety or impropriety of extirpation in the early stage. It is probable that the disease is both local and constitutional, that is to say, local in the onset, and constitutional as the disease advances; though, perhaps, some cases may happen in which it may be constitutional *ab initio*. The majority of surgeons now act on the principles which guided Mr. White in the advice he gave (see the case of Mary Meek). It is not wise, neither is it necessary, to meddle with an indolent scirrhus; an operation may, by the excitement it causes, be the means of rousing the dormant mischief in the system, should it prove a constitutional affection; even merely handling the tumour rather frequently may precipitate its termination into the open cancer. But when the occult malady shows signs of activity, when the integuments become inflamed, or when commencing ulceration is evident, it would be highly advisable to proceed at once to its extirpation, ere the chain of glands becomes affected, ere there is much ulceration or constitutional disturbance. Without it, the patient is sure to die a lingering and painful death; the operation affords a chance for safety. No surgeon would do his duty unless he explained such circumstance to his patient, and also the risk: there is of a relapse, then let her decide for herself.

Supposing, now, that the operation has been performed, and the patient has recovered from its effects; she may either live for many years, and at last die of another complaint, or the disease may return within a longer or a shorter period, and destroy life. It has been known to re-appear in the cicatrix itself, ere it was formed. The cancer thus reproduced has been extirpated, but of course unavailingly. The majority of surgeons are against and reprobate the performance of such an operation, as the relapse proves the disease to be constitutional, and not to be eradicated by surgical means, and consequently a second operation is merely inflicting additional suffering, without any real prospect of advantage.

The usual time, when a relapse of the cancer is expected to take place, should it occur, is about a twelvemonth after the operation, from that to two or three years, but even after the lapse of ten years it has again showed itself, and occasionally it has been known to occur, as has been already stated, ere the cicatrix had been formed. When a relapse has occurred, the scirrhus becomes ulcerated much more speedily than in the original complaint. Instead, however, of appearing in the same situation, the disease may occasionally attack other parts of the body;

the other breast, for instance, or the uterus, but in neither case can any thing be done in the way of a cure. The palliative plan of treatment is alone feasible, and alone to be adopted; the patient is, we may say always, doomed, surgery can do nothing for her.

On laying open a cancer, after it has been excised, it presents the following appearances: the structure is laminated, crossed by transverse ligamentous bands, or what appear to be such; in the centre there is generally a softish pulp, while all around is firm; the cellular tissue in the neighbourhood is generally diseased, and occasionally there are radicles striking into the adjacent parts, the whole of which must be removed, or the operation will be infructuous. When the disease is more advanced, and before it has proceeded to the stage of external ulceration, the softened pulp in the centre has disappeared, and its place is filled up by that sanies, which is afterwards abundantly secreted from the surface of an open cancer. The vicinal chain of glands, when enlarged, partake more or less of the same structure as the disease of the breast, and some of those, which are more mature, may contain sanies. In extirpating these, when an operation is performed under such unfavourable circumstances, it is not enough to cut out the glands themselves, but their connexion with the mammary tumour must also be removed, or a relapse will assuredly take place, and the operation prove of no advantage to the sufferer. The extent of incision would be frightful, and the chances of ultimate safety are so poor, that perhaps after all it were better to let it alone.

CASE I.—Cancer of the Right Mamma.—Sarah Tuck, ætat. 47, was admitted July 23rd into Anne's Ward, under Mr. Guthrie, for cancer of the right breast. She is a short and very fat woman, of the leuco-phlegmatic temperament, and so much alarmed at the idea of an operation, that Mr. Guthrie remarked, that if it were not done within half an hour after her admission, she would run away from the hospital to avoid it. She is a servant at the University of Cambridge, married, and has borne a child. The menses are regular.

The disease commenced about eight months ago, and the tumour, at the date of her admission, possessed the characteristic hardness, with retracted nipple, and lancinating pain. The axillary glands were enlarged.

Mr. Guthrie removed the breast, including the nipple, with a double elliptical incision, made rather obliquely; this having been effected, the glands in the axilla were cut out, and several portions of fat, which presented an unhealthy, or suspicious, appearance; the pectoralis major was bared, and part of it cut away with the disease; one or two vessels were then tied, and the ligatures cut short; a central one was then passed through the integuments, to keep the labia of the wound in apposition; large straps of adhesive plaster

were then applied; pressure with the hands, duly and regularly sustained, was directed to be exerted on the parts for four hours, with the view of preventing secondary hæmorrhage. Mr. G. observed, that where this was properly done he had never known any ulterior bleeding occur. The plan proved ineffectual, however, in the present instance; on the second day after the operation slight hæmorrhage occurred, and again, on the 27th, blood was lost to the amount of half a pint; on both occasions it stopped spontaneously. Hysterical symptoms supervened soon after the operation, and were removed with great difficulty. She survived about a week, but did not rally. On examining the breasts, no attempts at healing appear to have been made by nature.

The friends would not permit the body to be opened.

CASE II.—Cancer of the Right Mamma.—Mary Meek, ætat. 47, attended at the hospital August 24, 1833, by desire of Mr. Lynn, sen., for a consultation to be held on her case. She is a tall and rather stout woman, of the leuco-phlegmatic temperament. The following statement was elicited during the consultation by her answers. [The consultation was held in the first instance between Mr. Lynn and Sir A. Carlisle in the theatre, and, afterwards, between Mr. Lynn and Mr. White in the shop.]

She resides at Clapham; is a nervous, irritable woman as regards her system; has been married twenty-two years, but has not had any children. Rather more than two years ago, she received a blow on the right breast from a door suddenly slammed to, the key, which was in the lock, striking her on that part. A tumour shortly afterwards formed, which remained nearly stationary until within the last two months, since when it has rapidly increased in size. She has been under the hands of an apothecary in her neighbourhood, by whom she was lately sent to Mr. Lynn, with an assurance that an operation afforded the only chance, and that but a poor one. Mr. Lynn expressed himself of the same opinion, but was willing to give her the chance, and, with that intent, directed her to come to the hospital for the consultation.

On examination there was found to be a tumour in the right breast, rather larger than the fist, unattached, save to the integuments, of a stony hardness, and sensible to the touch; veins in the neighbourhood enlarged and partly varicose; skin of a leaden hue, save near the nipple, where it is ulcerated and inflamed; nipple retracted; she complains of lancinating pain in the breast; glands in the axilla not enlarged, nor is there any other apparent affection of the system; the uterus and other viscera do not present any indications of disease. She menstruates regularly, and says she enjoys good health.

The history of the case having been thus obtained, she was directed to withdraw, when

Sir A. Carlisle expressed himself as unfavourable to an operation. He remarked that he had never known a case terminate favourably after an operation had been performed; the disease had always returned, and terminated the life of the sufferer. He had known patients live ten years with a cancer; he instanced the case of Mrs. Gordon, who had been one of the incurables in that hospital for two and thirty years, with five cancerous sores, and at last died of old age. Hæmorrhage, he remarked, took place occasionally from the surface of the sores, and then the pain abated. He finally expressed it as his opinion that all operations, and more especially those on the breast, in irritable subjects, like the woman whose case was under consideration, were likely to terminate unfavourably. With this opinion Mr. Lynn appeared to coincide, and it was finally arranged that the palliative treatment alone should be had recourse to, unless the woman herself became exceedingly anxious to be freed from her burden, in which case she should be admitted into the hospital and an operation done. In this intent she was provided with half-a-dozen of Mr. Lynn's pills, to take one or two occasionally.

Just as the woman was on the point of leaving the hospital, Mr. White arrived, and having been informed of the nature of the case, became anxious to see it. Accordingly Mr. Lynn led the way to the shop, where a second consultation was held. The preceding statement having been recapitulated, and Mr. White having examined the breast, and satisfied himself as to the nature and present condition of the scirrhus, the woman was desired to leave the dispensary, and then Mr. White gave his opinion. He considered the case to be fit and proper for an operation, because the rapid growth of the tumour was recent, it was not adherent, and there was not any disease in the neighbourhood, her general health likewise was good; an additional and forcible reason was that the disease was putting on its most malignant aspect. He would not amputate a breast if the tumour were quiescent, because it might remain so for some time, but as soon as it became irritable, and inclined to ulcerate, as was evidently the case in the present instance, the sooner the operation was performed, the greater was the chance for the patient; he was of opinion that it would prolong her life, and keep her quiet a longer time.

These different opinions were communicated to the woman, and she was informed that, if she made up her mind for an operation, she would be admitted into the hospital.

Nothing more was heard of her until Sept. 14th, in the same year, when, having finally decided on submitting to amputation, she was admitted under Mr. Lynn, and forthwith brought into the theatre. Mr. L. removed the breast by a double elliptical incision, including between the two cuts the whole of the tumour and the nipple. As the operation

proceeded, Mr. White, who assisted him, placed his fingers on the orifices of the bleeding vessels, which were not tied until the tumour was completely removed. Three ligatures were applied; the cellular tissue was so far excised, that the pectoral muscle was laid bare. The patient displayed great courage during the operation, but required a little wine towards the latter end. The lips of the wound were drawn together with strips of adhesive plaster, and the patient was put to bed.

15th. Passed a tolerable night, and is nearly free from pain; complains that the bandage feels rather tight, which she considers gives rise to a similar sensation of tightness in the chest. There is not much action in the system; pulse small, but not feeble; complains of slight pains in the loins; bowels not open; had a saline draught this morning. Wishes for fish for dinner, which was ordered for her.

17th. Is much the same, with very slight reaction; the pulse is very small, and scarcely to be felt; does not rest well, and is very nervous, dreading the pain of dressing the wound; she experienced but little, however, as the bandage was cut, and the dressings softened and well soaked with warm water, before they were removed. Adhesions were found to have taken place in part, while suppuration was forming in the centre; bowels open; appetite little.

23rd. She is now taking ammonia with gentian and aromatic confection; suppuration moderate; the ligatures have separated to day, the 16th after the operation.

25th. Has four ounces of wine daily at her own request; has a mercurial sore mouth, caused by one of Lynn's pills which she has taken.

28th. Doing well; wound healing; mouth still sore. Is very anxious to leave the hospital; recommended to stay a little longer, more especially on account of her sore mouth, but she refused.

She came afterwards once or twice to the hospital to show herself; the wound was quite cicatrised, and there were then no symptoms of a return of her complaints. About two or three months ago, however, we learnt from a surgeon who was attending her at Mitcham, where she then was, that the disease had returned in other parts, and she was then dying. We have not seen the gentleman since to ascertain the termination of the case, but little doubt can be entertained as to the fatal result.

CASE III.—*Ulcerated Cancer of the Right Mamma—Death.*—Emma Hollingsworth, ætat. 49, residing in Little Marylebone-street, was admitted into Anne's Ward, Oct. 15th, 1833, under Sir A. Carlisle. Is a tall and rather thin woman, of the atrabilious temperament; is a widow; has been married nineteen years, but has never borne children; six years ago the change of life occurred, marked by occasional floodings, and sometimes by complete absence of the menstrual

secretion for months. About twelve months after her dodging time had commenced, she was admitted into the Westminster Hospital with rheumatic fever, and she says that during her convalescence she perceived a small tumour form in the right breast, moveable, and without pain, but "as hard as a marble." It increased in size very slowly for the first two or three years, and during that time she remained free from pain. Two years ago she became the subject of lancinating pain in the tumour, which began then to increase much more rapidly. A twelvemonth past she had some leeches applied, with the hope of relieving the pain; the bites did not heal, and in a short time an open cancer was established.

On her admission, she presented a tumour of the right mamma, about the size of the fist, of stony hardness, with retracted nipple, enlarged and varicose veins, and the integuments altered in colour, adhering to the diseased gland, which appeared to be unattached to any of the subjacent tissues. There were several clefts in the integuments covering the tumour from which issued a sanious fetid discharge; there was also an irregular ulceration, of the size of a crown piece, also bedewed with the cancerous ichor. It was considered that some of the axillary glands were enlarged, but this was not ascertained to the satisfaction of all who examined her. The chain of glands running along the upper and lower margins of the pectoralis major were apparently normal.

Her general health is much affected; she is much emaciated; appetite failing and rest broken; there was not any symptom of any other disease being present in the constitution.

She was admitted into the hospital principally because she had been a servant of Sir A. Carlisle's, under whose care she was placed. She was resolutely determined that no operation should be performed, but was willing to try the effects of any remedy that could be proposed. It would be useless to trace the diurnal progress of the case. Soon after her admission, iodine was employed, both externally and internally; and the ioduretum ferri was given, but without any benefit. While she was taking these medicines, the ulceration enlarged, the discharge increased in quantity, and became more and more fetid, the tumour became adherent to the surrounding parts, the axillary glands evidently participated in the disease, and her life was one continued scene of misery. Mr. White's attention was drawn to the case about this time, and he recommended the free application of the potassa fusa, so as to destroy all the fungoid and unhealthy parts; this was done three or four times with the effect, as he prognosticated, of rendering the ulceration clear and apparently healthy, of altering the nature of the secretion, and of alleviating or nearly removing the pain for a time. Its effects were,

however, merely local; the constitutional symptoms were becoming almost daily more severe and threatening; the countenance constantly wore an anxious and depressed look; rest could only be obtained by the use of morphia; her appetite was lost, and she was wasting to a shadow, in fact, the tenure of existence seemed held only by a thread, when, early in September last, she was attacked with erysipelas, followed by profuse suppuration, from the immediate effects of which she recovered, but the extreme debility induced by it, and the long and painful continuance of her cancer, remained, and she sunk on the 18th of November, 1834. The body was not examined.

To these cases may be added one of carcinomatous tubercle of the face, although it does not seem to be in exact relation with the preceding.

James Bryant, ætat. 51, residing at Bracknell, in Berkshire, was admitted into Mark's Ward, under Mr. White, Dec. 8th, 1832. About twelve months previous he perceived a small pimple on the left side of the nose, which became ulcerated, gradually enlarging until it was as large as a sixpence. When admitted it gave him little pain, but that was decidedly lancinating. The ulcer had hard, and rather everted edges, with irregular depressions and elevations in its cavity, without any indications of granulating, presenting, Mr. White said, the appearances of the carcinomatous tubercle. His general health was unaffected.

While the man remained in the hospital, Mr. White made a few remarks on the case, which may be here introduced. He observed that the disease was more analogous to the tubercular fungoid tumour of the breast, in young females between twenty and thirty, than to true cancer; he added that on the face and lip, destructive agents and excision would prove more permanently successful than in other parts; nevertheless, he had seen the glands in the neighbourhood enlarged, and containing that peculiar matter which indicated its origin from the parent stock (cancer).

Within a day or two after his admission, a consultation was held relative to the performance of an operation, which was deemed impracticable, on account of the situation of the ulcer, which covered the lachrymal sac, extending up close to the tendon of the orbicularis palpebrarum, and it was feared that the latter would be injured in excising the disease. The nitras argenti was accordingly applied in substance, a very fine point being applied occasionally on the surface. The first effect was to remove the hard and everted edges; contraction and cicatrisation afterwards took place, the lower part of the ulcer healing before the upper. He was discharged well, on the 29th of Jan., with directions to return should a relapse occur. Upwards of a year and a half has passed, and no tidings have been received of him.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, Feb. 19, 1835:—Alfred John Spencer, Belper, Derbyshire; Joshua Ingham Ikin, Moer Allerton, near Leeds; Griffith Davies, Dolgelly; Thomas Henly King, Calne, Wilts; Francis Hales Skurray, —; Jas. Eckley Pattison, Taunton, Somersetshire; Frederick Collins Noble, Knowlesworth; George Broad, Penzance.

MISCELLANY OF FACTS.

Will of Baron Dupuytren, relative to the new Chair of Pathological Anatomy at the Paris School of Medicine.—Orfila has sent a letter to one of the French daily papers, in consequence of an article on Dupuytren which had appeared in it, and in which he was alluded to. Some errors had crept into the article in question, which M. Orfila desired to be set right. He says that on the 24th October, Dupuytren, in the presence of M. and Madame de Beaumont, requested his advice relative to that clause in his will by which he bequeathed 200,000 francs to the School of Medicine, with the view of founding a chair of pathological anatomy, and also stated his wish that Cruveilhier should be the first professor. Orfila suggested that the sum should be devoted to the formation of a museum of morbid anatomy, to be called the Musée Dupuytren, as well as the chair. This proposition met with the approbation of Dupuytren, and also of Cruveilhier, to whom it was afterwards submitted. It should seem by some remarks made afterwards by the testator, that he so thoroughly adopted the proposition for the museum, as to be desirous that his nephew should hold an office in it; yet by some extraordinary and unaccountable accident, the original provisions in the will, directing the foundation of a professorship only, were not altered, and consequently the museum is out of the question.

Anatomy—Scarcity of Subjects.—A meeting of the medical students at Edinburgh took place on Saturday week, in the Waterloo Rooms, for the purpose of taking steps to obtain a better supply of subjects for dissection. It should appear that the parochial authorities have in some instances thrown obstacles in the way of the students, which are only to be explained by the supposition of the existence of the most narrow-minded prejudice that ever beset mortal man. The substance of the resolutions which we append will show that the complaints of the Edinburgh students are identical with those which have been just redressed in London. We do not doubt but that they will be equally attended to. The pupils intend petitioning parliament, and also memorialising the Secretary of State on the subject. The resolutions were to the effect, that the Anatomy Act is defective, inasmuch as it does not render it imperative upon parochial authorities, managers of hospitals, &c., to deliver up their unclaimed dead, and that consequently many are buried which might be rendered available to the student of anatomy, without prejudice to the feelings of any, while at the same time it would obviate the complaints, that the few which they at present receive are unequally distributed among the different medical schools.

APPOINTMENTS.

Naval.—Mr. Oughton, assistant surgeon to the Revenge.

Military.—Mr. Opie Smith has been appointed veterinary-surgeon of the 11th Light Dragoons, in place of Mr. Cherry, deceased. Assistant-Surgeon Wm. Harvey, of the 9th reg., to the 9th Foot, v. Drysdale, appointed to the Staff. Staff Assistant-Surgeon David Ewing to be assistant-surgeon to the Rifle Brigade, v. Woodford, who has resigned. Hospital Staff—The following have been appointed Assistant-Surgeons to the Forces:—James Murray Drysdale, from the 9th reg., v. Ewing, appointed to the Rifle Brigade; Archibald

Alexander, gent., v. Palmer, appointed to the 92nd reg.; John Drope M'Ilree, gent., v. Fraser, appointed to the 6th reg.; and Neil Stewart Campbell, gent., v. Tuthill.

General.—Mr. Lister, surgeon to the Halifax Dispensary. Dr. Paley, physician, and Mr. Earle and Mr. Alfred Smith, surgeons to the Ripon (new) Public Dispensary.

Resignations.—Mr. Nunn, apothecary to the Western Dispensary. Charles Strut, Westminster. Mr. —, resident apothecary and accoucheur to the Farrington Dispensary and Lying-In Charity, Giltspur-street. Staff Assist.—Surgeon Woodford, of the Rifle Brigade. Mr. Hedworth, surgeon to the Leeds General Eye and Ear Dispensary. Dr. Fitzpatrick, physician to the Bedford General Infirmary.

DEATHS.

Dr. James Stenhouse, of Comely Park, Dumfermline. Dr. Wm. Thompson, of Essex-place, Princes road, Kennington. Veterinary-Surgeon Cherry, of the 11th Light Dragoons. Mr. John Taylor, of Birmingham, surgeon, aged 81. Dr. W. Smith, of Upton Magna Hall. In Taunton, Dr. Thompson, formerly of Chudleigh. John Denny, Esq., of Ipswich, retired surgeon of the 62nd Foot. At Spanish Town, Jamaica, Dr. D. Thompson Dempster, formerly of Cupar, N.B.

CORRESPONDENTS.

Syntax.—His critique on a formulary in a contemporary journal is not suited for our pages.

Quicksilver Jack.—We have our eye upon him.

Medicus.—We believe it is not absolutely necessary that the Thirty-Nine Articles should be subscribed to in order to become a Fellow of the College of Physicians.

An Apprentice should consult with some legal adviser upon the best mode of proceeding.

Dr. Bacon.—We believe his communication to be all gammon.

Communications have been received from J. Y. on Metro-peritonitis, *A General Practitioner* on Fungus Hematodes, *Dr. Foote* on Delirium Tremens, *Dr. Gambal* on the Pulse, and a peculiar case of otitis treated by stimulants, which shall be inserted *quam citissime*.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

*At the Meath Hospital during the Session of
1834-5.*

LECTURE I.

GENTLEMEN,—As it is usual, at the commencement of a course of clinical instruction, to devote the first lecture to a consideration of some general topics connected with the line of studies most proper to be pursued by those who wish to attain eminence; I have, in compliance with this custom, thought it right to lay before you some observations on the proper mode of studying physiology and morbid anatomy, with a view of showing how best to derive advantages from these accessory but necessary sciences, sciences which, according to the manner in which they have been cultivated, have at different periods retarded, or advanced, that most important of all branches of professional knowledge, practical medicine. It is quite evident, that a knowledge of the functions and structure of the body in health is essential to him who undertakes the treatment of disease, and hence physiology has always occupied the attention of physicians. Physiology, however, may be studied in very different ways, and with very different objects, and, until lately, all those who were engaged in the cultivation of this fascinating science, not contented with observing the state of the different parts and tissues during health, the nature and quality of the secretions, the mechanism and operation of the different organs, sought to ascend from a knowledge of effects to an investigation of causes, and, after they had classified the more obvious phenomena of living bodies, endeavoured to ascertain, if not the very principle of life, at least those motions and causes of motion which result immediately from the action of the living principle. Having thus, as they conceived, obtained a more accurate knowledge of the conditions of health, they proceeded to form general explanations of

the causes of disease, and frame general rules for their removal. This method, apparently so philosophical, and possessing so many attractions from the generality and simplicity of its application, has more than any other circumstance contributed to retard the progress of medicine. Gentlemen, this is not only an ancient, it is also a modern, evil. We live among systems. It is true, that the practice, founded on the mechanical, mathematical, chemical, and humoral physiologies, has been long since abandoned; but the destructive system of Brown has not long quitted the stage, where its place is occupied on the Continent by those of Broussais and Rasori, and in Great Britain by the system which derives all diseases from derangement of the digestive function, or from inflammation. Physiology legitimately embraces not the study of vital actions but merely aims at ascertaining and arranging their effects. The important facts, which its study discloses, are perhaps infinite in number. As long as we confine ourselves to these we advance at every step, and all is clear and intelligible; but the moment we attempt to enquire into the causes and modes of vital action we begin to retrograde, and all becomes hypothesis and confusion. Thus, an examination of the organ of sight discovers a wonderful and beautiful optical arrangement, calculated to form on the retina a picture of external objects, exact both in its colouring and outline. The physiologist, examining with attention the different parts of the eye, and the laws of their respective refractions, investigates the means by which distinct vision is secured at different distances; he compares the human eye and its appendages with that of animals which live in water, those which soar into the highest regions of the atmosphere, and those which burrow under ground. He considers the eye of the mole, feeble but protected against injuries likely to be encountered in carrying on its subterraneous works; of the eagle who, poised high in mid-air, selects its victim from the distant pasture; of the fly, whose microscopic organ, with a range of vision scarcely exceeding the limits of contact, distinguishes objects the most minute, and in all he finds variations in the optical instrument at once curious and

intelligible. But when he endeavours to advance further in his inquiry, and tries to explain how an image, painted on the retina, produces vision, whether by the means of undulations arising from the rays of light, and propagated along the optic nerve to the brain, or whether because the retina is a nervous expansion, highly organised and framed, so as to feel the coloured image painted on it, he is at once arrested in his progress by the barrier which is every where interposed between physical and vital actions, between the mechanism of the organs of sense and the mode in which they produce ideas between body and mind.

But has he, therefore, gained no real knowledge applicable to practical purposes, or has his time been merely spent in a pleasing but useless study? By no means;—being acquainted with the mechanism and arrangement of the optical instrument, he is often enabled to remedy its accidental derangement. By means of a concave glass he corrects a too speedy, by a convex a too tardy, concentration of the rays of light. When the crystalline lens becomes opaque, his knowledge of its connexions, nature, and position enables him either to remove it altogether, or to displace it from the axis of vision, or to promote its absorption, and, in order to effect the latter purpose, he mechanically irritates it, knowing by experience, that, after such an irritation, the process of absorption commences, although he is quite ignorant of the connexion between mechanical irritation and this vital process. He who inquires into the physiology of the brain and spinal marrow can never discover the nature of nervous influence, or the manner in which pressure on these organs destroys, or irritation deranges, the motions of the voluntary muscles, and yet the entire treatment of cerebral or spinal diseases, whether spontaneous, or from the effects of injury, is grounded on a knowledge of this physical fact; without it we could not estimate the value or effects of morbid changes in the brain or spinal marrow. On this reposes the rationale of the treatment of all convulsive, paralytic, and apoplectic affections.

Although we know not the manner in which the eighth pair of nerves superintends the respiratory process, although we understand not how the phrenic nerve influences the motion of the diaphragm, yet a knowledge of these facts led to a relief of spasmodic asthma, and to the recovery of persons apparently asphyxiated, by means of the Galvanic stimulus passed along the course of these nerves. Knowing that some of the nerves, distributed to the face, are destined for sensation, while others serve for muscular motion; in cases of tic douloureux we divide the sentient and not the motive nerves. In these, and a thousand other instances, physical physiology supplies us with information at once interesting and practical; it would be still easier to prove, as in the cases of Brown and Broussais, that vital physiology, by involving us in the dis-

ussion of subjects beyond the powers of our reason, never fails to entangle its votaries in a labyrinth, amidst whose mazes they move without progressing, and consume in idle speculations that time and labour they ought to spend in the acquisition of useful knowledge. But I trust the period is at length arrived when this error will be avoided; for, on the whole, it must be confessed, that in consequence of a wrong method of studying, and a misconception of the true objects of physiology, this science has in many instances retarded the progress of practical medicine.

Let us next consider the connexion of morbid anatomy with practical medicine. Many have mistaken the end and object of morbid anatomy, and there are not wanting some who even deny its utility, while others again, in their zeal for its improvement, have endeavoured to extend its limits, so as to make it comprehend and embrace in the explanations it affords all the phenomena of disease. It is not easy to determine which of these parties has most injured the cause of practical medicine. Morbid anatomy comprehends not merely decided and permanent structural alteration, but embraces, so far as they are capable of being detected, even temporary physical changes in internal organs. In order justly to estimate its importance we should recollect that the first alteration in the texture of a part is not the cause but the consequence of disease, for in every healthy organ the texture is natural, and as every change of texture is produced in consequence of derangement in the vital action of the vascular system of the part, it is obvious that structural alteration must in the first instance be always produced by functional derangement. Thus the physical alterations which attend external inflammation; the tumefaction, the heat, the redness are not the causes but the consequences of disease. But in thus reducing them to the rank of symptoms, do we diminish their importance? Certainly not. For being immediately connected, as effects, with the primary cause, they prove the most useful of all symptoms, in enabling us to ascertain the seat and progress of diseased action. In this respect they possess a manifest advantage over the general or constitutional symptoms. Thus, in cases of spontaneous gangrene, phlegmonous inflammation, or erysipelas, what practitioner would be contented to draw his indications from the general symptoms, disregarding the appearance of the affected part? and yet this is exactly what those persons do who refuse the aid of morbid anatomy in the treatment of internal disease.

In external diseases most of the physical changes in the affected part can be at once recognised; their diagnosis is therefore comparatively easy, and their treatment well established. In internal diseases the case is widely different, the physical alterations are here beyond the cognisance of our senses; and, in order to ascertain their nature and situation,

we must carefully compare the morbid appearances of internal organs, as revealed to us by dissection, with the symptoms during life. Although alteration of structure is in the first instance produced by a disease in the vital action of the part, yet this structural alteration may itself become a new cause of mischief. Thus the vascular system of the lungs, from some unknown cause, assumes such a change of action as produces a deposition into the pulmonary texture of various fluid and solid products, by which the entrance of the air into its vesicles is prevented, and the respiratory function, one of the most important of the body, is thus considerably deranged. Again, whatever be the original vital derangement which causes scirrhus of the pylorus, the obstruction thus formed is a secondary cause of new and important symptoms. Another consideration, which enhances the value of morbid anatomy, arises from the fact, that when diseased action fixes itself in any part of the body, whether external or internal, and there gives rise to physical alterations, experience teaches us, that the progress of the disease may be often arrested by removing its effects. Thus, to recur to the example of external inflammation, the redness, the swelling, the heat of the part are but symptoms, and yet we find great benefit from the applications of remedies capable of diminishing them; hence we leech, and apply cold lotions, &c. From all these considerations it is evident, that whenever disease is attended with either a temporary, or a permanent, alteration in the tissue of an internal organ, it will be of the greatest practical importance to ascertain the nature and extent of that alteration, and the progress of practical medicine will be exactly proportioned to the accuracy with which this can be accomplished. Thus, how much has the treatment of pectoral diseases been improved by the application of auscultation and percussion, means which are only useful by enabling us to ascertain the physical alterations induced by the disease, or, in other words, the morbid anatomy of the affected organ. Without their aid, how trace the progress and follow the increase or diminution of pulmonary inflammation?—how demonstrate the existence of dropsical or pleuritic effusion within the chest?—how detect latent pneumonia?—how distinguish with certainty pleurodyne from pleurisy? I could prove the utter impossibility of distinguishing many cases of bronchitic from tubercular phthisis without their assistance. I might refer to chronic emphysema of the pulmonary tissue, a disease of great importance, but actually unknown before the time of Laennec, who first accurately described it in the dead body; indeed, before the application of percussion and auscultation, a perfect knowledge of this derangement of the pulmonary structure in the dead body would not have assisted our diagnosis, for how recognise it during life? I might bring forward dilatation of the bron-

chial tubes, another disease wholly unknown before Laennec's time, and which, before his discovery, could not be recognised by the common method of observation. I might enlarge upon the great utility of attending to the changes which take place within the chest in measles and scarlet fever, but the benefit resulting from an accurate acquaintance with the morbid anatomy of the thoracic cavity is now so generally acknowledged, that I shall rather choose my illustrations from other classes of diseases.

Nosologists, until very lately, were agreed in attributing considerable frequency to those cases of apoplexy and paralysis, which arise from serous effusion into the brain, or from a mere functional inaction or debility of the cerebral and nervous systems. This opinion was founded partly on speculative grounds, and partly on inadequate and imperfect post-mortem examinations, and in practical books the symptoms supposed to announce sanguineous, serous, and nervous apoplexy were dogmatically laid down. What was the consequence?—Most disastrous, as I have had occasion to witness, in some parts of the continent, where the elderly practitioners still adhered to the practice founded on this false pathology. What can be more melancholy than to see time wasted or misemployed in the exhibition of diuretics, to promote absorption of the serum effused into the brain, or of strong exciting remedies, such as arnica, camphor, &c., to overcome the nervous debility, in cases where copious depletion by the lancet and purgatives were urgently necessary. I do not deny that in some rare cases effusion into the brain is the cause of sudden death from apoplexy. I have seen such an event supervene in chronic dropsy, but there the termination was very sudden, and the state of the case left no doubt as to the cause; but in the majority of the cases formerly treated as serous or nervous apoplexy a more careful examination would have detected marks of vascular excitement, or local inflammation, a subject I shall treat at large when on the pathology of the brain. A similar error in morbid anatomy led to a similarly erroneous practice in the treatment of hydrocephalus, and many cases of general and local dropsy. The effusion occupied the sole attention of pathologists; the marks of preceding vascular excitement or inflammation escaped their notice.

Time will not permit me to enlarge upon the light which morbid anatomy, rationally pursued, has shed upon diseases of the brain. It is sufficient to remark, that some of the most important modifications of inflammation in that organ have been only lately discovered, and it is only lately that a minute and extensive examination of the different changes the brain undergoes in disease, has begun to introduce a certain degree of regularity and precision into a department where all before was confusion and inaccuracy. Examples of

the utility of morbid anatomy might be brought forward without number:—the discovery of local inflammation being at times the cause of a disease in most of its symptoms resembling common ague; the use of the lancet in the cold stage of ague, a practice which may be advantageously resorted to, in cases where each return of the fit is accompanied by a recurrence of inflammation in a vital organ, as the lungs or brain; the connexion between inflammation of the mucous membrane of the stomach, and some of those symptoms of fever formerly attributed to mere debility; the influence of cerebral inflammation and congestion, in producing the symptoms formerly vaguely denominated typhus; the low character which fever assumes when accompanied by pneumonia (and that, too, often latent); the symptoms which are produced by follicular ulceration of the intestines, which so frequently occurs in the course of fever; the diagnosis between the pain produced by neuralgia of the abdominal nerves, and that resulting from structural diseases of the intestinal canal; a more accurate knowledge of the state of the mucous membrane in the diarrhoea of phthisis, and in intestinal tympanitis; the numerous improvements in the treatment of diseases of the ear, which followed Itard's investigations concerning the morbid anatomy of that organ;—these and many other discoveries, all replete with practical advantages, are the results of the attention of our contemporaries to morbid anatomy; and, were I to appeal to the records of surgery, I might bring forward examples, if not more important, perhaps more evident and striking, for the invention and success of most capital operations depend on a perfect knowledge of the structural derangements, the removal or cure of which is attempted. Of this, examples suggest themselves on every side, but none is more striking than the one devised by Dupuytren for the cure of artificial anus, the most disgusting and loathsome malady to which human nature is subject, and deemed altogether incurable, until that excellent surgeon, by a combination of profound pathological and physiological knowledge, succeeded in planning and executing an operation, that were alone sufficient to immortalise his name.

The study of morbid anatomy, however, is attended with no ordinary difficulties, and, when imperfectly understood, is liable to lead to erroneous results, for it requires much candour, much patience, and that experience which can be only acquired by long continued practice, to enable us to judge concerning diseased appearances. The power of accurately discriminating in the dead body the traces of disease cannot be suddenly acquired, and so numerous are the various errors to which superficial observers are liable, that much injury has thus resulted to medical science, diseased appearances being in some cases overlooked, and in others recorded where

they did not exist. Those who are aware how often the congestion, which frequently takes place immediately before or after death, in the pulmonary tissue, in the mucous membrane of the lungs and alimentary canal, and who know how often this congestion alters the physical properties of these parts, so as almost exactly to simulate the vestiges of inflammation, will understand how it happens that in investigations connected with the real or supposed diseases of these parts, facts have been marshalled against facts, and observations arranged against observations, until the path which promised simplicity and order terminated in perplexity and confusion. Hence the doctrines of Broussais received so many corroborations, and appeared to rest upon a numerous series of undoubted and well authenticated facts.

The morbid anatomist must of all things beware of seeing too much. He must avoid imposing on himself by everywhere seeing exactly what he expected to see, and above all things let him not always force himself to see something; for many diseases proceed to a fatal termination without having produced any evident morbid alteration.

When I come to treat of the pathology of the brain and nervous system, I shall have occasion to advert to errors which late authors have committed from too great an anxiety on the one hand to reduce to a certain and definite system the morbid appearances of the brain and spinal marrow, as connected with their diseases, and, on the other, to find, in every case where the cerebral or nervous functions had been diseased, lesions of structure to account for the symptoms. Thus, to cite one of numerous instances, I shall have occasion to prove that epilepsy and mania often commence suddenly and violently, without the existence of any organic alteration; and, indeed, that organic lesions are not necessarily connected with these formidable diseases is sufficiently proved by the occasional sudden manner in which they cease. Thus, a gentleman of great literary reputation was many years a patient of mine before his death, which happened in 1831, at the age of seventy. From the age of twenty-five to fifty-five he suffered from violent and frequently recurring fits of epilepsy; after having continued thirty years the disease ceased suddenly, without any assignable cause, and for the last fifteen years of his life he had not a single fit. I shall have occasion to show you how fine-drawn and how ill-founded the observations of those who profess to account for every nervous disturbance during life by cerebral lesions, who profess to distinguish accurately during life inflammation and irritation of the arachnoid or dura mater from irritation or inflammation of the brain itself, who maintain that one series of symptoms is produced by inflammation of the cortical, and another by inflammation of the medullary, substance, who have strained their eyes to discover, and their veracity to

impose upon us, proofs that inflammatory or other diseased states of certain portions of the brain caused invariably similar affections of certain mental functions. These errors of some, even of the most eminent French pathologists, it will be my duty to notice from time to time; but I am sorry to say that much more unpardonable errors and misstatements have found their way into English and Irish publications on the pathology of the brain, and which I shall be compelled to speak of hereafter.

Having made the preceding observations on the dangers which arise from an ill-directed application of the studies of physiology and morbid anatomy to the practice of medicine and surgery, I feel myself imperatively called on to present the other side of the question to your view, in exposing the still more dangerous doctrine advocated by those who depreciate the value of pathology and morbid anatomy as only instructive after the death of the patient, and even then as not unfrequently calculated rather to mislead than to advance the interests of practical medicine.

It must be conceded that he who is only a physiologist cannot hope to cure disease, and that the mere morbid anatomist will be often misled by post mortem appearances, if he has not attentively watched the progress of symptoms and the effects of medicines during life, for, unless this be done, he will, as I have already said, often mistake secondary for primary lesions, will confound effects with their causes, and will refer to certain alterations of structure that which had originated in a functional disorder, a morbid state of parts very different from that which is observed after death. But when, to an accurate knowledge of physiology and morbid anatomy is joined an extensive observation of the progress of symptoms and the effects of therapeutical agents, how much more certain and satisfactory will be our practical decisions, and how much more likely our efforts to be attended with success, than if we merely studied disease at the bed-side of the patient. In the latter case, we might indeed become expert nosologists, be accurately acquainted with certain groups of symptoms, and even not unfrequently adopt the proper method of treatment. These symptoms, considered together, we would call by a certain name, and hand down to posterity this new acquisition of medical knowledge, perhaps clothed in the garb of a dead language, and invested with the false dignity of a learned tongue. But what have we really thus effected for posterity?—Our followers read our definitions of disease with an acquiescing admiration, and, sure of the efficacy of the remedies we have recommended, they go forth with an overweening confidence in the quest of the group of symptoms we have described, and when they have met with them they look upon their task as already half accomplished, and promise a successful termination of the disease. "Tell me the

name of the disease," was the motto of the nosologist, "and I will tell you the remedy;" but, gentlemen, I will engage to tell you the names of a hundred diseases, without your being able to name the proper method of treatment. I tell you a man has dropsy, his limbs are anasaruous, water is accumulated in the peritoneal cavity, his urine is scanty, and his thirst increased. Will you, from this very excellent nosological definition, venture to prescribe for this case of dropsy? For the sake of the suffering patient and your own conscience, prescribe not on such data. And yet I regret to be obliged to say, that such a method of proceeding is by no means rare, nay, it is even a matter of daily occurrence. But this case of dropsy will not yield. Some other boasted specific hydragogue or diuretic is had recourse to; still the patient grows worse and worse, and finally dies, but his friends are not discontented with the medical attendant, who excuses himself by asserting that he has successively resorted to every remedy which has been recommended in dropsy; and in truth if you look over the list of medicines exhibited in rapid succession, you will probably find that his excuse is not unsupported by facts. But, gentlemen, these cases in which every thing has been tried, are exactly those in which nothing has been tried, in which medicine has followed medicine, and each symptom of disease has indiscriminately been the object of attack, until death approaches with accelerated steps, and charitably closes a scene distressing to humanity, and disgraceful to the cause—I was going to say—of science, but who will venture to give so ennobling a name to this pseudo-practical knowledge, this worse than absolute ignorance?

Gentlemen, I am not combating phantoms; I do not, Quixote-like, contend with imaginary giants; no, gentlemen, what I have described exists, the picture I have drawn has many an original. But let us have done with this subject; let us turn to the gratifying considerations of the progress which practical medicine is making under its parent science,—physiology and morbid anatomy.

The reason of man is now more fully employed than at any former period, a vast store of mental power, a vast mass of mind is everywhere at work; what formerly was vainly attempted by the labour of a few, is now easily accomplished by the exertions of the many. The empire of reason, extending from the old to the new world, from Europe to our Antipodes, has encircled the earth—the sun never sets upon her dominions,—individuals must rest, but the collective intelligence of the species never sleeps; at the moment one nation, wearied by the toils of day, welcomes the shades of night, and lies down to seek repose, another rises to hail the light of morning, and, refreshed, speeds the noble work of science!

All inquirers commence, as it were, at the same point, as the labours of their predecessors are equally at the disposal of all, and conse-

quently it is not surprising we should often find them arriving together at the same end; thence the numbers of simultaneous discoveries of the same fact now so common. It is not unusual to find the publications of France, Germany, Italy, and England, simultaneously announcing the same discovery, and each zealously claiming for their respective countrymen a honour which belongs equally to all. I am sorry to say that, with some splendid exceptions, this interesting and innocent controversy has been carried on by other countries, while Ireland has put in no claim for a share of the literary honours awarded to the efforts of industry or genius. But, gentlemen, I hope that this state of inaction, this state of mental torpor, has ceased, and that the time has passed away when we could not point out among our brethren any who had advanced the boundaries of the medical sciences, and thus promoted the interests of humanity. Already have the names of several of the senior members of the profession been spread abroad, already has the scientific character of this city been elevated by such men as Dease, Blake, Colles, Carmichael, Cusack, Crampton, Marsh, and Kirby; and already have some of the junior members of the profession attached their names to discoveries which shall be commemorated as long as anatomical sciences are cultivated; I need scarcely add that I allude to the names of Jacob and of Houston. The interesting descriptions given by these gentlemen of their respective discoveries, in a department of human anatomy in which all further discovery was looked upon as hopeless, are probably known to you all, and therefore it is unnecessary now to enlarge upon them. Neither have we, at present, leisure to enter into the no less interesting field of investigation which Dr. Corrigan has opened by the publication of his experiments on the sounds and motions of the heart, experiments leading to conclusions so novel, that most physiologists were at first incredulous, and many even ventured boldly to call into question their accuracy. Without at present venturing to decide whether Dr. Corrigan's opinions be in every respect correct, I may assert, that his paper is written in the true spirit of philosophical inquiry, and that he deserves opponents of a far higher grade than those who have endeavoured to refute his arguments in the English periodicals.

With regard to the treatment of disease, we must not omit the discovery, by Mr. Carmichael, jun., of this city, of the curative effects of spirits of turpentine in iritis, for although we were in possession of two valuable remedies for the cure of this disease, belladonna and mercury, yet there are cases in which it is useful to be able to accomplish a cure without the aid of salivation.

It is with feelings of the greatest satisfaction and pride, that I claim the right of adding to this list the names of three gentlemen whose friendship I have long enjoyed, Mr. Adams,

Mr. McDowell, and Dr. Stokes. Of the two former it is unnecessary to speak, their contributions to science are so well and so duly appreciated. Concerning the latter, my colleague Dr. William Stokes, I shall impose upon myself an unwilling and constrained silence, partly because his merits claim a warmer and longer eulogy than would suit this time and place, but chiefly because his labours have placed him in a position, as far elevated above the necessity of praise, as above the fear of censure*. Neither shall I allow myself to eulogise as they deserve the talents and exertions in the cause of science rendered by Professors Apjohn, Harrison, Kane, Montgomery, and E. Kennedy. They all rank high among the successful cultivators of some of the most useful departments connected with our art; their names, associated with those already enumerated, form a catalogue the subject of congratulation for the present, of happy augury for the future, for cold must be the breast of him who will not hail with joy every symptom of our country's literary regeneration, dead the feelings which are not elated at the boon conferred on our species by every advance made by those who devote themselves to the grand, the noble, pursuit of relieving the suffering, of healing the diseased; but time bids me stop, I shall, therefore, conclude by observing that the attention lately devoted to the distinctions between real and pseudo-morbid appearances, the diligent cultivation of morbid anatomy by men not the slaves of preconceived opinions, the abandonment of all systems whose baseless fabric rests on the phantoms of vital physiology, the importance now justly attached to medical statistics, to the study of endermic and epidemic maladies, to the operation of morbid poisons; these, and various other circumstances, give us reason to hope that the progress of the human mind in investigating the means of preventing and curing diseases, will not be less rapid than it has been in the other departments of knowledge; and thus it will be proved that if man has passions which impel him to the destruction of man, if he be the only animal who, despising his natural weapons for attack or defence, has devised new means of destruction, he is also the only animal who has the desire or the power to relieve the sufferings of his fellow-creatures; the only animal in whom the co-existence of reason and benevolence attests a moral as well as an intellectual superiority.

* If praise from a praiseworthy person, the "*laudari a laudato viro*," be an enviable distinction, how desirable, on the same principle, must be the censure of Mr. Wakley.

LECTURES

ON

MIDWIFERY & THE DISEASES
OF WOMEN AND CHILDREN,BY EDWARD RIGBY, M.D., F.L.S.,
ASSISTANT PHYSICIAN-ACCOUCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXI.

*Mechanism of Parturition—Presentations of
the Face and Nates.*

GENTLEMEN.—At my last lecture I endeavoured to explain the manner in which the head of the child presents at the beginning of labour, and the course it takes in passing through the pelvic cavity and outlet. From what I then told you, you will perceive that there are two positions of the head, in both of which the sagittal suture corresponds to one of the oblique diameters; in the most common the occiput is turned to the left foramen ovale, in the other to the right foramen ovale, with the exception that in this position, during the early periods of labour, it is turned to the right sacro-iliac synchondrosis, and gradually moves forwards as labour advances. Whether or not the first position in many cases is originally the fourth, as the second is at first the third, is difficult to say, but, from the interesting observations communicated to me by Mr. Blount, of Birmingham, and from some cases which I have met with, it does appear that, at an early period of labour, the head is more frequently in the fourth position than has been imagined, but that it soon passes into the first or most common, viz. with the posterior fontanelle forwards and to the left.

Before describing to you the manner in which, according to Professor Naegele's extended experience, and my own observations, the face presents at the beginning of labour, it will be necessary to give a short enumeration of the various positions in which the face is said to present by the schools and systematic works on midwifery. Four presentations are usually enumerated, two with the *chin* more or less forwards, viz. the first with the chin corresponding to the left, the second to the right acetabulum, and two with the *forehead* more or less forwards, corresponding to the left acetabulum in the third, and to the right in the fourth position, as the chin did in the two first. We are told that in the first and second positions, as the head advances through the cavity of the pelvis, the chin gradually turns forwards towards the pubes, and by the continued pressure of the uterine contractions rises up sufficiently behind it so as to allow the forehead to descend and pass over the perineum, which it distends immensely, and clears the external opening with great difficulty. In the two last positions, the chin undergoes the same movements as the forehead has done in

the two former ones; the forehead rises up behind the pubes, and the chin sweeps with great difficulty over the perineum. These are the four positions of the face according to the German schools, but Baudelocque, and after him the French authors, have added two other presentations where the face is in the antero-posterior diameter of the pelvis. "Of all those," says Professor Naegele, "I have only seen the two first, and I speak from considerable experience, for a great number of face presentations have come under my observation. As I allow of only two presentations of the cranium, in like manner I can allow but two of the face, the chin to the right, and the chin to the left, which, although exactly contrary to the order of face presentations, according to Stein, Siebold, &c., yet I have the satisfaction of knowing that the experienced Madame La Chapelle agrees with me*."

According to the experience of Professor Naegele, and those cases which I have myself had an opportunity of observing, that position of the face is the most frequent, when, at the beginning of labour, the forehead is turned towards the left ilium; in this case the right side of the face is that part which presents, the zygoma and eye being nearly in the middle, and situated lowest in the pelvic cavity; as the os uteri gradually dilates, what in the first position would have been the sagittal suture is here the root of the nose, and this is what the finger first touches upon, as it enters the os uteri. The swelling which the face brings with it into the world is situated upon the right cheek, exactly as in the first position of the head, it is on the superior and posterior quarter of the right parietal bone. As in this position the posterior fontanelle gradually moves from left to right, so now in the present case the chin moves from right to left, and passes under the pubic arch.

In the second position of the face, the forehead is turned towards the left ilium, the chin more or less to the left foramen ovale; it is precisely the contrary of the first position; the left cheek and zygoma are lowest in the pelvis, and the chin moving from left to right passes first under the pubic arch.

In the third and fourth positions of the face, according to the German schools, where the forehead is turned towards the pubes, as the face enters the pelvis, being too broad and too flat to pass under the pubic arch, it is, by the continued pressure of the uterine contractions, forced upwards behind the symphysis, and the chin with great difficulty sweeps under the perineum, which it distends enormously.

Now this, gentlemen, is evidently impossible; for, if you consider but for a moment, you will find that to allow the head to pass under the pubic arch in this manner, would require a neck of, at least, *seven inches* in length.

The two positions which Baudelocque de-

* MS. Lectures.

cribes, where the long diameter of the face is said to be in the antero-posterior diameter of the pelvis, are still more ridiculous, for it will be evident that in such a position there must be a moment when the head with its perpendicular, and the breast with its antero-posterior, diameter, are at one and the same moment engaged in the antero-posterior diameter of the pelvis. Now the former measures three inches and a half, and the latter, two inches and a half, making in all a diameter of six inches, and this to pass through an aperture which, even in the skeleton, measures only four inches and two or three lines. In Guillemeau, Mauriceau, La Motte, Levret, Stein, &c., in whose works an immense number of cases have been recorded, you will find no such case as that I have now mentioned. What speaks still more against it is that Madame La Chapelle, the most experienced person whom the annals of midwifery have yet produced, who did not become an authoress until she had actually observed upwards of *forty thousand* labours at the Maternité of Paris, declares that such a case is impossible. The engraving of such a position which is in Smellie's plates, and which seems to have been the foundation of Baudelocque's description, is, as La Chapelle rightly observes, merely a seven months' foetus, where the cranial bones were little more than cartilage, and where the head was squeezed into a form more like a sausage than anything else I can compare it to. It was also described to have been born with great rapidity.

In the former century, presentations of the face were always considered as preternatural, and not capable of being terminated without artificial assistance; thus we find that Smellie, Stein, Osiander, and other distinguished accoucheurs of that time, turned the child in these cases. Baudelocque tried to push back the face, and bring down the vertex, but if this did not succeed (which was almost always the case), he either turned the child, or extracted it with instruments, and thus numbers of children were sacrificed. Portal was the first who considered that a presentation of the face differed but little from a natural birth, "except that the face of the child commonly appears black, which is easily removed by fomentations." "This delivery," says he, "is very troublesome to the mother, from the external parts being more distended than in any other labour." La Motte remarked that the pains in presentations of the face "were generally violent and without intermission, but," says he, "I have never seen any that have not done well." Nevertheless, if the pains were weak, and the child not far advanced in the pelvis, he recommends searching for the feet and turning the child. Giffard also recommended turning, although when called to cases where the head was already low in the pelvis, he generally applied his extractor.

Such, gentlemen, was the practice in cases of face presentation, from the time of Portal,

in 1685, till 1770, when Deleurye again brought his views into notice, and declared that the head in these cases could be born by the natural powers. After him, Boer, of Vienna, supported the same opinion in Germany, although opposed by Stein and Osiander; but it was not until the beginning of the present century that presentations of the face entirely ceased to be considered preternatural; so far from being preternatural, there are more living children born in cases where the face presents, than where the nates or feet present; nevertheless, these are decidedly not so favourable as where the cranium presents. In presentations of the cranium, where there is a slight diminution of proportion between the head and pelvis, the progress of the labour is but little affected, whereas, in cases where the face presents, the most trifling unfavourable circumstance of this sort will present serious difficulties to the passage of the head. Thus, for instance, the difference of half an inch in the antero-posterior diameter of the pelvis is of little consequence in cases where the cranium presents; the labour, it is true, will be prolonged, but the child will be born healthy and active, whereas, under similar circumstances, where the face presents, the child will generally be born dead. Many reasons have been assigned why children are occasionally born dead in face presentations; some have imagined that the spinal marrow was injured by the long and forcible degree of extension to which the neck was exposed. Osiander asserted that it was from the air coming in contact with the face some time before the head was born; the child was thus excited to make inspirations, but from the pressure was unable to continue them, and therefore died. Professor Naegele has examined several children, which have died during labour where the face presented, but has never found the least air in the lungs. Smellie has noticed the real cause in the explanation to his 25th plate. "But if the head is large, it will pass along with great difficulty, whence the brain and great vessels of the neck will be so much compressed and obstructed as to destroy the child." Chaussier, the celebrated physician to the Maternité at Paris, has examined these cases with great attention, and has uniformly found the cerebral vessels gorged with blood.

So much, gentlemen, for presentations of the face; I now come to those of the *breech* or *nates*, and, following the same arrangement as I have done when speaking of positions of the head and face, I shall now briefly enumerate those positions of the nates which are described in systematic works, and will then give you a more accurate and, I trust, more simple view of them as they usually occur in nature. Four positions are described; the two first with the abdomen of the child backwards, the two last with the abdomen forwards. In the first position, the abdomen and anterior surface of the child are turned

towards the *left* sacro-iliac synchondrosis. In the second position, the abdomen, &c., are turned towards the *right* sacro-iliac synchondrosis; in the third, they are turned towards the *right* foramen ovale; in the fourth, they correspond to the *left* foramen ovale.

According to the works on midwifery, as the nates pass through the pelvic cavity, the right ischium (in the first position) will gradually turn towards the pubes, but not being able to pass under the pubic arch, and as the left ischium has more room in the hollow of the sacrum, the right rises behind the pubes, while the left ischium passes over the perinæum; the shoulders turn into the antero-posterior diameter of the pelvis, the right being behind the pubes, the left in the hollow of the sacrum; the head follows with the chin upon the breast, and the chin being in the hollow of the sacrum comes first over the perinæum in the same manner as the left ischium did.

The third and fourth positions of the nates, viz. where the anterior parts of the child are turned forwards, are considered to be more unfavourable than the first and second, on account of the chin being apt to quit the breast, and lodge upon the symphysis pubis.

With respect to the diagnosis, we are told that a discharge of meconium, and the being able to feel the head in the fundus of the uterus, are signs of a nates' presentation; but we must not rely on these alone, for, as you are well aware, the meconium will frequently escape, where the head or other parts present, if the child be dead. The ischium is also said to be diagnostic of a presentation of the nates, but it is so thickly covered with flesh, that to distinguish the nates by this alone is impossible, because it may be very easily mistaken for a shoulder, or even parts of the face. As in presentations of the face, the nose is the only sure diagnostic mark, so here it is the inferior extremity of the sacrum, which not only serves to show that it is a nates' presentation, but enables us to distinguish which *species* of presentation it is. With respect to the parts of generation, as a means of diagnosis, nothing can be more deceptive.

According to Professor Nægele's experience, presentations of the nates may be classed under two heads; first, where the back of the child is turned forwards towards the anterior parietes of the uterus; secondly, where the back of the child is turned towards the posterior parietes. In both cases, one usually finds the back of the child at the beginning of labour turned more or less sideways, namely, the ischia running parallel with one of the oblique diameters of the pelvic entrance. The first chief division occurs more frequently than the other; but at the same time the difference between the two is not great. The feet originally are always situated in the vicinity of the nates, and at the beginning of labour are sometimes felt at the same moment. If, however, they

are situated rather higher than the nates, as these descend into the pelvis the feet rise upwards, are turned on the abdomen and breast of the child, and in the course of the labour are born with them at the same time; but if they be situated somewhat lower, they slip down before the nates. Hence it is evident that presentations of the knees and feet have been originally presentations of the nates; in fact, those of the knees cannot be considered as a distinct presentation.

"In every case, whether the nates have at first a completely transverse or oblique direction, they will be always found, on pressing lower into the superior aperture of the pelvis, to have taken an oblique position, and that ischium, which is directed anteriorly, to stand lowest. They pass through the entrance, cavity, and outlet of the pelvis in this position, which is oblique, both as to its transverse diameter as well as to its axis. Thus, if in the first species the left ischium were either originally directed more or less forwards, which is usually the case, or had taken this direction in passing through the superior aperture, the nates descend in this direction into the pelvic cavity, with the left ischium during the whole time standing lowest; and this is the part, during the further progress of the nates, which first passes between the labia as the os externum dilates.

"As they advance, and while the left ischium, which is directed forwards and always somewhat to the right, comes completely under the pubic arch, and presses against it; the other ischium, which is situated in the opposite direction, and which has to make a much greater circuit, passes forwards over the strongly distended perinæum, so that when the pelvis is born the abdomen of the child will be directed to the inner and posterior surface of the mother's right thigh. The rest of the trunk follows in this position; and, as the breast approaches the inferior aperture of the pelvis, the shoulders press through its superior aperture, in the direction of the left oblique diameter; and during its passage, (viz. the breast through the pelvic outlet,) the arms and elbows, which were pressed against it, are born at the same moment. But, whilst the shoulders are descending in the above-mentioned oblique position, the head, which during the whole progress of the labour rests with its chin upon the breast, presses into the superior aperture in the direction of the right oblique diameter, viz. with the forehead corresponding to the right sacro-iliac synchondrosis, and then into the cavity of the pelvis in the same direction, or one more approaching the conjugate diameter; after this, it presses through the external passage and the labia in such a manner, that, whilst the occiput rests against the os pubis, the point of the chin, followed by the rest of the face, sweeps over the perinæum as the head turns on its transverse axis from below upwards.

"But it is sometimes the right ischium

which in this chief division is either originally turned forwards or in the process of time assumes this direction. In this case the child passes the pelvis in the same manner as before, only with this difference, that the surface of the body takes of course a different position with respect to the pelvic parietes, viz. its anterior surface, which in the former case corresponded to the right side of the pelvis, will be here directed to the left, and the head will press through the superior aperture of the pelvis in the direction of the left oblique diameter, the forehead passing before the left sacro-iliac synchondrosis.

“As in positions of the cranium the swelling of the integuments is chiefly met with on that parietal bone which, during the passage of the head through the pelvis, is situated lowest, and on that spot with which it enters the external passage, so in this case the livid-coloured swelling appears on that part which, directed forwards, was situated lowest during the passage of the nates, and with which the nates were born.

“In the second chief position, viz. with the anterior surface of the child corresponding to the anterior abdominal parietes of the mother, it is chiefly the left ischium which is either originally situated forwards, or takes this direction as the nates sink through the superior aperture of the pelvis, which latter preserve this oblique direction during the farther progress of labour, both whilst pressing into the pelvic cavity and when entering the external passage. If the ischia be already born, the anterior surface of the child turns itself to the right and backwards, either immediately or as the rest of the trunk advances, so that the manner in which the head in this case presses through the entrance, cavity, and outlet of the pelvis, is the same as has been already described.

“It not unfrequently happens, that, in this species of nates presentation, the right ischium is either originally directed forwards or takes this direction. In this case the nates will move through and clear the pelvis in the same manner as before, only with the difference, of course, that the anterior surface of the child will be situated forwards and to the left. The child also makes a turn, as in the other case, either immediately after the nates have passed through the os externum, or when the rest of the trunk has advanced further, only that here its anterior surface will turn backwards and to the left; in like manner, also, as the head presses through the superior aperture, the forehead will here descend, corresponding to the left sacro-iliac synchondrosis*.”

Thus you see, gentlemen, that in presentations of nates, whichever way the body of the

child may be turned at the beginning of labour, yet, if the progress of labour be not interrupted, the head, as it enters the pelvic cavity, will always turn, so that the forehead shall correspond to one or other sacro-iliac synchondrosis. In no presentations is so much mischief done by unnecessary interference as in those of the nates; the position in which nature has placed the child is the most favourable possible for its passage through the pelvis, and any attempt to alter it runs the risk not only of rendering labour more tedious, but of putting the child's life in the most imminent danger. The chin, during its passage through the pelvis, will constantly remain pressed upon the breast, and will have the effect of directing the head into and through the pelvis in the most favourable position. The arms remain pressed upon the breast; the soft passages, from the gradual advance of the child, are dilated sufficiently slowly, so as to oppose less resistance to the head as it follows, and, from the progress of the labour being sufficiently slow, the uterus will be but gradually relieved of its contents, its contractile power increased, and itself rendered capable, by means of sufficiently powerful exertions, of forcing the head into and through the pelvis within a proper time.

As far as the mother is concerned, presentations of the nates are scarcely, if at all, more unfavourable than those of the head, but for the child it is very different; if circumstances occur, by which the head is at all delayed in its passage through the pelvis, the cord is liable to be compressed, and the child thus destroyed. What keeps the chin upon the breast? the action of the uterus acting upon the lever, which is formed by the long diameter of the head; if the accoucheur tries to hasten delivery by attempting to pull the child, what is the result? The uterus ceases to press upon the head, the chin leaves the breast, as there is now a free space beneath the chin, the arms, which were before crossed upon the breast, slip into it, and then pass up on each side of the head; the head, moreover, comes with its long diameter into the cavity of the pelvis. In those cases, where the anterior surface of the child has been turned forwards, and the head has been described to have come first with the occiput over the perineum, we may be tolerably certain that this has been the result of pulling.

Presentations of the nates and feet must be reckoned among natural labours; there is certainly, during one part of the labour, a period of considerable danger to the child, viz. when the head is passing through the pelvis, for at this moment the umbilical cord is liable to be compressed, and hence it is why presentations of the nates are more dangerous than those of the face. Presentations of the feet are decidedly not so favourable for the child as those of the nates, although they are much easier for the mother; where the child comes double, as in nates' presentations, the pass-

* Mechanism of Parturition. Although Dr. Dewees does not coincide with me as to the mechanism of labour in nates presentations, still the order in which they occur is precisely the same.

ages are more distended, and it opposes a greater resistance to the efforts of the uterus, which is thus excited to more powerful exertions, and this is an important point. On the contrary, where the feet present, the opposition is much smaller, the trunk is born rapidly, but the head remains behind; for, at this critical moment, if the uterus has been suddenly emptied of part of its contents, the pains will cease; hence, although footling cases are less painful, they are much less desirable than nates' presentations. On the whole, therefore, as long as the pelvis is well-formed, the child not too large, and the pains good, there is every chance of a successful termination; but, if the contrary be the case, the labour is prolonged, the cord becomes compressed, and the child is lost. One favourable circumstance, connected with the nates' presentations, is, that they seldom occur in first labours.

With respect to the degree of frequency with which the various presentations, which I have described in this and the preceding lecture, occur, the average, taken from a very large number of labours, is, of a hundred births, a child will present with the cranium in ninety-three or ninety-four times, about four times with the nates, or feet, but the face does not present more than once in two hundred times.

ON THE PROXIMATE AND EXCITING CAUSES OF PHLEGMASIA DOLENS.

BY J. H. HORNE, ESQ., M.R.C.S.

IN order that all the phenomena of any particular disease may be satisfactorily accounted for, or acknowledged by the profession, it is highly desirable that the causes of the disease should be established. I believe this has not been effected in the present subject, hence there have been sufficient grounds for the opponents of a distinguished member of the profession, Dr. Robert Lee, to doubt, or even object to, what the Doctor has advanced respecting the pathology of phlegmasia dolens. The acknowledged interest of the subject, and the diversity of opinion among medical, especially our obstetrical, writers, respecting the causes of it, will be considered, I hope, a sufficient apology for my endeavouring to direct the attention of the profession to these essential points.

The various causes hitherto assigned by authors for the production of phlegmasia dolens, are translation of the lochia (Mauriceau), translation, or deposit of milk in the affected part (Perzos and Levret), morbid condition of the lymphatic vessels (White), rupture of the lymphatics (Frye), or inflammation of all organs except the bones (Hull),

pressure of the gravid uterus during pregnancy (Dr. D. Davis).—See Dr. Ryan's Manual of Midwifery, 3rd edition, page 651. Since the disease, within the last few years, has been more thoroughly investigated, and cases have occurred after suppressed menstruation and abortions, it is acknowledged that these are not sufficient to account for it. Dr. Lee attributes various causes for the production of phlegmasia dolens, viz. "suppressed menstruation, malignant ulceration of the os and cervix uteri, as well as some other organic diseases of the uterine organs." These diseased conditions of the uterus cannot be assigned as the causes of the affection, but should, I think, rather be considered as occurring occasionally in conjunction with it, for cases of suppressed menstruation and malignant ulceration of the uterus may be seen daily, but not the least traces of the disease under consideration are to be found with them. Or if we admit these conditions of the uterus as the causes of phlegmasia dolens, we must also admit, I think, that polypus, carcinoma, and the cauliflower excrescences of the uterus are the causes of leucorrhœa; whereas every member of the profession is well aware, that these malignant affections are frequently traceable to neglected or maltreated cases of that disease.

Mr. Cruickshanks remarks, in a note to Mr. Frye, of Gloucester, quoted by Dr. Lee, in his excellent work on some of the most important Diseases of Women, page 147, that "they have imputed the swelled limb, which happens after lying-in, to a *dépôt-de-lait*, but it is owing to something wrong in the constitution," which is a remarkable fact; but it has not been, I think, attempted to be pointed out what this something wrong in the constitution originates from; therefore it will be my province at least to attempt to point out what it is. How far I may succeed in effecting this desirable object I must leave the profession to judge.

Having taken this cursory view of the subject, I trust I shall now be able to prove, that my hypothesis of the primary cause of the affection, is founded on that deranged condition of the morbid parts that we find after death, and which alone, I believe, can be promulgated as satisfactorily accounting for the disease, whether it occurs after menstruation, abortion, or parturition.

I maintain, then, that the proximate cause of phlegmasia dolens arises primarily from a deranged condition of the menstrual function, causing an undue action in the vessels concerned in the production of this necessary secretion, and from the constant source of irritation kept up by the speedy return of the periodical function, that a morbid state commences in the minute ramifications of the hypogastric veins, which gradually extends, as the source of irritation continues, along the course of the iliac and femoral vessels, and by degrees a thickening of the coats of the vessels follows; and in those cases which terminate fatally, after the disease has become fully de-

veloped, a perfect obliteration of their canals is found from a deposition of fibrinous and earthy matter, demonstrable by chemical analysis.

I have attempted for some time to overturn this hypothesis by arguments and practical facts, but there are none that I have been able to produce which can possibly account for the extraordinary fact, that this most interesting, and, when genuine, most destructive disease, which not unfrequently manifests itself in a few hours, and almost within as short a period proves fatal, and what immense disorganisation of vessels we find, after these speedy and fatal cases, at the post mortem inspection; and how actively engaged must have been the organs concerned in manufacturing the immense mass of disease that exists. If we do not admit that something wrong in the constitution has been set up for an indefinite time, gradually progressing, as stimulated by the source of irritation, the deranged function of menstruation, proved by the return and increase of pain in the hypogastric region, and along the course of the crural vessels, at each period of the catamenial secretion, or how can we account for the phenomena of this disease, that otherwise would appear to be produced at a time when all the functions of the body are in a great measure suspended.

It has long since appeared evident to me (I may have been mistaken), that those who have favoured us with their views on phlegmasia dolens, have for the most part allowed their attention to have been too much rivetted to that time when the disease generally makes its appearance, viz. after parturition, or during the period of utero-gestation. But this process, I believe, is no further concerned with the disease than the debilitating effects arising therefrom, and it matters not, however naturally or easily the labours may have been performed; for within twenty-four or forty-eight hours after the best accomplished ones, it is frequently our distressing lot to witness the greatest degree of debility ensue; and it is this debility that seems so admirably calculated for developing phlegmasia dolens, which does also, we find, supervene, either after high febrile or constitutional disturbance, from suddenly suppressed menstruation, or after abarctions; and if my hypothesis of the proximate cause be maintainable, we shall also, I think, be able to prove the exciting cause, viz. debility.

Before I give in detail a few cases of phlegmasia dolens in support of what I have advanced, I beg leave to observe, in order that I may not be mistaken, that a sudden suppression of the menses by the common exciting causes, such as cold, sudden fright, febrile action, are not sufficient, as far as my observations have gone, to produce it, unless the catamenia have been previously affected, and the necessary morbid change has taken place or commenced, either in the hypogastric, iliac, or femoral vessels, and this morbid change, I

presume, is the something wrong in the constitution hinted at by Mr. Cruickshanks, which I alluded to before, and have now, I hope, satisfactorily explained or accounted for.

CASE I.—A female, aged 27 years, residing in St. Martin's-street, Leicester-square, consulted me in 1832, who I found had suffered from painful menstruation nearly from the beginning of its first appearance, and, for the last seven or eight years, from being constantly exposed to the depressing effects of the nocturnal vicissitudes of the atmosphere, her general health had become greatly debilitated, and the catamenia scarcely ever appeared without the sufferer experiencing fresh attacks of cold, with increase of pain, and difficulty attending it. In April, a total suppression of the menses occurred, followed by violent fever, high constitutional derangement, accompanied with great tenderness of the hypogastrium, thigh and calf of the right inferior extremity, with enlargement and loss of power in that limb. Suddenly the fever assumed the typhoid character, and the consequent debility my patient's shattered frame could not withstand, and death ensued a few hours after the typhoid fever set in. The post mortem appearances confirmed the disease. The coats of the common external iliac, femoral, and hypogastric veins of the affected side were thickened, and the canals of the two former vessels were almost completely plugged with firm coagula. Evident marks of recent inflammation were traceable in the different veins in the immediate neighbourhood, and, by pressure, pus exuded from the open cut mouths. The uterus appeared healthy, with the exception of being softer and more flabby to the feel.

Old and recent marks of inflammation were discovered in almost every viscus of the body. This patient had never been pregnant.

CASE II.—A well-marked case of phlegmasia dolens came under my observation in the spring of 1833, after an abortion, the pregnancy advanced about three months. She had for some years previously suffered severely, during the menstrual period, with considerable pain in the left inferior extremity, and accompanied, prior to the catamenia appearing, with great pain and fulness of the veins of the same limb. Her health had been declining apace for some months. Phlegmasia dolens became fully developed in the evening of the second day after the abortion. The pain was so excruciating, that the patient could neither move the limb, nor suffer it to be touched. She remained between forty and fifty hours without stirring or speaking, unless roused. The treatment consisted almost solely of a liberal use of cordials, with powerful sedatives, to abate the pain. She recovered, but the limb had not regained its natural appearance by the ensuing autumn. The swollen, flabby, putty-white appearance, with a bluish tint, and exquisitely tender to the least impression made on the thigh over the direction of the great

vessels, well marked the characteristic features of the disease.

I regret exceedingly it has not been in my power to procure a preserved specimen after an abortion, but the fact is they are very rare, and which I think may be accounted for from the debility induced after an abortion, which is not to that extent as after parturition; hence recovery generally follows. Among the numerous specimens, beautifully illustrating the pathology of phlegmasia dolens, in the possession of Dr. Lee, there is not one, I believe, after an abortion.

CASE III.—A poor girl, scarcely twenty years of age, became pregnant by her lover, who soon after deserted her. She concealed the fact from her parents; and as she had suffered from difficult menstruation, and it had also been irregular for some years, she willingly took, by their advice, powerful emmenagogues, such as aloes, pennyroyal, steel wine, hiera-picra,—remedies well known to, and in the reach of, every old woman, in the hope of their procuring abortion. However, they proved of no avail, but rather tended, in conjunction with her dejected mind, to produce great debility. I delivered her at the full period of utero-gestation. After delivery, which was natural, her weakness, pain and numbness in the right inferior extremity, greatly increased. By opiates and cordials these threatening symptoms were checked. The second week after confinement her friends were compelled to change their residence, and the fatigue induced by transporting her from one place to another dreadfully increased the debility, and shortly after phlegmasia supervened. From her constitution being naturally good, and herself young, she recovered, but the affected limb remained almost useless for many months. Stimulants internally, hot fomentations, wrapping the limb in flannel, followed by frictions, and bandaging it, were the principal means adopted for the recovery of the limb.

I might attempt to occupy the pages of this Journal, by relating numerous other cases that have occurred and proved fatal, after either condition, could I conceive for a moment that they would prove either advantageous to our subject, or the members of the profession, as little dependance, I am fully aware, are placed on them in general, owing to many points being omitted in order that they may be brief; in proof of my assertions, I could cite upwards of twenty fatal cases of phlegmasia dolens which have been published, where the condition of the menstrual function, prior to the attack, has not been once referred to. However, perhaps I may be permitted to allude, in a few words as possible, to those cases which occur occasionally almost within the first month after parturition, and after the effects of that process have been apparently recovered from, in persons of pretty tolerably robust con-

stitutions, where they have been suddenly seized with high febrile symptoms, debility ensuing quickly ushering in the disease under consideration, and not unfrequently proving fatal.

It has been difficult to account satisfactorily for these cases, and I think it will still remain so, unless we admit that it owes its first origin to a diseased state of menstruation, and before the disease can be brought into action, the system must labour under general debility, its exciting cause. In conclusion, it remains for me to acknowledge the assistance I have received from the valuable labours of Dr. Lee and Dr. D. Davis, and to express my thanks to you, gentlemen, for your kindness in giving insertion to this communication.

Reviews.

The Dublin Journal of Medical and Chemical Sciences, including the Latest Discoveries in Medicine, &c. No. XIX.

THE Dublin Journal is as replete as ever with original and interesting communications. The first article is "Pathological Remarks on Chronic Abscesses, by Dr. M'Dowell." The Doctor prefaces his remarks with the subsequent observations. "Chronic diseases of the bones, or of the joints, frequently terminate fatally, by inducing acute inflammation of the serous membranes, or by the formation of purulent deposits, in some of the important organs, occurring, as in the brain, lungs, liver, &c, or purulent infiltration of the cellular membrane may result from long continued, or severe, irritation of a mucous membrane, as of the bladder."

Three cases are presented as exemplifications. One will suffice to develop the view which the Doctor takes.

"CASE II.—Cornelius O'Neil, aged 36, admitted April 6th, 1832, with prominences of the seventh and eighth dorsal vertebræ; lower down, tenderness upon pressure, incipient transverse sulcus of the abdominal parietes; impaired power of the lower extremities; occasional pains shooting from the loins to the lower limb; muscles flabby; cough and slight mucous expectoration; frequent and troublesome flatulence of the abdomen; impaired appetite; perspirations, &c. Previous history: six years and a half since laboured under syphilis, for which he was salivated several times; about the same period pains commenced in the middle and lower part of the dorsal vertebræ, with weakness in the limbs; a year since he was thrown from a horse, and this accident was followed by an increase of pain; he has been blistered eight times; cauterization was applied on either side of the diseased vertebræ, and the bowels carefully regulated.

"May 8th. Pain now extends along the

margin of the false ribs towards the sternum; increased weakness; numbness and coldness of the lower extremities; dyspeptic symptoms are also worse. During the succeeding four or five months blisters and tartar-ematic ointment were applied without relief. He left the hospital, and was not seen until April 4th, 1833, when the following report was made:—
 ‘Increased stiffness of the back; shooting pain from the back down the right thigh; swelling of the right knee-joint, with contraction of the leg, from slight synovitis; tense and lymphatic abdomen; appetite failing; bowels regular; urine passed freely. Three months subsequently a lumbar abscess became developed on the right side, small but tense, ointment of the hydriodate of potash was liberally applied to the tumour, and for one month there was much relief, the tumour appeared to lessen considerably, but again increased, and, on examination, the abscess was found to have extended to the inguinal region, forming a swelling internal and inferior to the anterior superior spinous process of the ilium; debility and numbness of the limbs increased; tumours and spine rather tender; bowels generally confined; suffered lately from influenza, and since that time cough, with expectoration, is more troublesome than formerly. I meditated puncturing the abscess, according to Mr. Abernethy’s plan, but the general want of success following this operation, when the vertebrae are diseased, deterred me; a blister was applied to the tumour in the loins, and the surface afterwards dressed with savine ointment; this caused so much local uneasiness, with irritability of the stomach, that the unguentum resinæ, and subsequently poultices, were applied to the blistered surface.

“Dec. 5th. Tongue white and furred; ardent thirst; constant vomiting; distended abdomen; tympanitic; not tender on pressure; pulse 130, and soft. Pills of calomel and opium; effervescing draughts, and an enema in the evening.

“6th. Insomnia; nausea constant, and severe retchings; hiccough; severe headach; pulse 120, feeble; cephalalgia; thirst continues; bowels free; urine high coloured; dyspnoea; pain referred to the region of the diaphragm; mucous rattle; had profuse perspiration during the night; sunken look; prostration of strength. A mustard cataplasm was applied to the epigastrium; thirty drops of laudanum in an enema, and the following directed:

“R. Mist. camph. ℥vj.
 Ætheris sulphurici, ℥jss.
 Sp. ammoniæ arom. ℥jss.
 Tinct. opii, ℥xl.
 Sumat coch. ampl. duo 4tâ horâ.

“7th. The sinapism did not act; bowels free; urine nearly of the colour of blood; cessation of vomiting; occasional singultus; pulse very rapid, upwards of 144, and still feeble, though less so than yesterday; profuse perspirations; respiration 24 in a minute, and

jerking; occasional cough, with mucous râle, continues; headach; looks still more depressed. Sinapisms directed to the feet.

“8th. No sleep last night; some raving; tremors; other symptoms as yesterday, more debility.

Vesicatorium inter scapulas.

Sinapisms repeated, an emollient enema, and four ounces of wine with water.

“9th. Constant moaning and raving during the night; pulse rapid and thready; eyes glazed; insatiable thirst; mucous râle louder and more diffused over the chest. Died this day.

“On examination, there was found an enormous flatulent distension of the cœcum; the colon was doubled on itself below the right lobe of the liver, and descended very low to form the transverse arch; the vermiform appendix was united by old and firm adhesions to the cœcum; the right kidney was displaced and pushed forward by the psoas abscess; liver soft, flaccid, and pale.

“Thorax.—On the right side intense and recent pleuritis, with purulent effusion; the inflammation was peculiarly acute below, where lymph in large quantity was poured out between the pericardium and lung, and between the latter and the diaphragm; the left lung throughout was firmly connected to the parietes of the chest by old adhesions; bronchitis; two ounces of serum in the pericardium.

“The pleuritis, in this case, was overlooked; no pain in the chest was ever complained of; uneasiness was referred to the epigastrium; and the constant vomiting led me to believe that the cause of irritation was below the diaphragm, and that it was connected with irritation of the sac of the abscess, consequent upon the application of the blister to the lumbar tumour.”

The next communication is by Dr. Churchill, entitled “Researches on Instrumental Delivery,” and was read before the College of Physicians. The author commences by congratulating the profession on the comparative infrequency of instrumental operations to that in earlier times, when the philosophy of parturition was less understood, and when the powers of nature in effecting delivery, even in very bad cases, was not properly estimated.

The cases requiring manual, or rather the employment of instruments, are divided into three classes. In the two first, the measures to be employed the author imagines are clearly indicated. In the one case you have a sufficiently capacious pelvis; the outlet is free, and the soft parts are in a condition to readily admit of the expulsion of the fœtus: but there is a want or a deficiency of uterine contraction. Such a condition may arise from a defective vigour of the whole system; the uterus, therefore, participating; or it may be dependent upon a partial paralysis—a want of power of the uterus alone; in such a case artificial means,

after the accustomed delay, are demanded. Here the use of the ergot of rye shall be resorted to. In this case the author conceives that "the substitution of an extractive force for the expulsive effort is manifestly all that is required." The conclusion is too abruptly arrived at. The uterus is, unquestionably, the most powerful and the most desirable agent for expelling the child, and those means which can be devised for restoring its full activity when impaired, are assuredly preferable to any extractive force applied by instruments.

In the *second class*, where there is a disproportion between the size of the foetal head and the capacity of the maternal pelvis, or where the pelvis is considerably distorted, artificial means are imperatively demanded for the extraction of the child. This condition forms a *class* of its own. Ergot of rye could not effect the object, no kind of forceps could be employed with safety, or with the probability of success. To craniotomy we must resort.

In the *third class*, when the woman has arrived at the full period of utero-gestation, and when any of the following contingencies arise, such as when "fever or inflammation sets in, or where there is great exhaustion; where similar effects result from the malpresentation or malposition of the head, or where the child is hydrocephalic, in cases of fainting, hæmorrhage, or convulsions; where tumours obstruct the passage, or where its calibre is diminished by deformity of the pelvis, but not to any great degree, or where the child is supposed to be dead;" for these cases Dr. Churchill enters into a long discussion on the comparative virtues of the *forceps* and *crotchet*.

We next notice a table of the relative number of forceps and crotchet cases. "Among British practitioners, the number of operations compared with the number of cases, are 167 in 29,195, or about 1 in 174. In 16,499 cases, there were 53 requiring the forceps, or about 1 in 311, and 64 requiring the crotchet, or about 1 in 257.

"In the estimates given by French authors we have 59,908 cases and 262 operations, or about $1\frac{1}{2}$ in 238. The forceps were used 221 times, or nearly in the proportion of 1 to 271. There were 41 crotchet cases, or about 1 in 1461. The relative frequency of the two operations is almost one crotchet case to five forceps cases." In Germany, the forceps cases are $1\frac{1}{2}$ in 67, and the crotchet cases about 1 in 752.

The object of these elaborate investigations is to enable us to form an estimate of the two instruments. And the author concludes, as many have done before him, that the forceps is the preferable instrument, and that in no case where the forceps can be practically employed, is the crotchet to be used. In using the crotchet we inevitably sacrificed the child, and it appears very naturally that the mortality of the mothers is greater, as we notice that it is. But the cases in which one or the other instrument is to be employed are so dissimilar,

that we conceive no difficulty could arise in distinguishing the most appropriate one. The Doctor rambles a little, he is not always clear and definite; the details, however, are worthy of record, and they support the conclusions he has made, that the forceps is the preferable instrument, and that the mortality is smaller from either, in skilful hands, than the majority of individuals might suppose.

"Cases and Observations," by Dr. Christian, forms the next article. A case of spitting of blood is first recorded, in which it appeared doubtful whether it proceeded from the lungs or stomach; it was found to have proceeded from the sockets of two of the inferior incisor teeth which had probably been swallowed and again ejected.

The next is one of *monomania* occurring in a young girl, apparently depending upon suppressed catamenia, uterine congestion, as remedies directed to that organ removed the malady.

A remarkable case of congenital malformation of the iris is noticed by Dr. Osborne, which was clearly hereditary. Practical Observations on Fever, by Dr. Little. On the Theory of Sleep is a well written and ingenious criticism of Macnish's theory, by Mr. Carmichael. History of a unique case of Heart Disease, by Dr. Hanna, is curious. Remarks on the Pathology of Abscesses on the surface of the Cheek, by Dr. Frorien, translated, with the ordinary concluding subjects, occupy this most valuable journal.

Descriptive Catalogue of the Preparations in the Museum of the Royal College of Surgeons in Ireland. By JOHN HOUSTON, M.D., &c., Curator of the Museum, &c. Vol. I. (Anatomy.) Hodges and Smith. October. pp. 250.

Next to possessing a good museum, is a catalogue which shall indicate the situation of each preparation, and describe its character and its nature. It would seem that the College of Surgeons in Ireland passed a praiseworthy regulation, directing that a catalogue of the various preparations in its museum should be made and published, with the object of facilitating the study of anatomy and diseased conditions. The present is the first volume, comprising a description of all the specimens which illustrate healthy anatomy; a second volume, representing diseased structures, is soon to appear. It is not merely a catalogue containing dry details of specimens, of unconnected descriptions, but a lucid and philosophical arrangement of healthy structure, as manifested in all the beings of creation; the classification is very similar to that adopted by Cuvier in his "Leçons d'Anatomie Comparée," there being but a trifling difference. It may perhaps be said by an Englishman, "of what utility is the Dublin College Museum to us, we cannot see the preparations,"—but the Irishman can, we answer, and it is for this

plain reason that a full notice shall be given of the work,—as fully, however, as our hebdomadal will permit; and, in doing so, we shall make long, or at any rate numerous, extracts, such as will induce, in the minds of Dublin men, a zest for examining the Museum, and afford interest to others, and may perhaps show them what preparations are curious, yet simple and easily prepared. The preparations are divided into those belonging to the “Organs of Assimilation,” “of Circulation,” “of Respiration,” “of Sense,” “of Locomotion and Prehension,” “Urinary and Genital Organs,” “Monsters,” “Animals.”

“A. a. 177. The tongue of an alligator (*lacerta allig.*). Its surface is smooth, without papillæ, and covered with a firm opaque cuticle. The nerves, exhibited on the lower surface, are remarkably large, and decussate in the mesian line,—their branches passing to supply the sides of the organ opposite to those at which the trunks are placed. The late Mr. Skeleton, who noticed this fact in 1822, has remarked, ‘that it is the most clear case of nervous decussation he is acquainted with.—J. S.—P. 18.

“A. a. 248. The head of a salmon prepared to show the teeth. It may serve as an example of a fish with teeth in every situation in which teeth are found in this class of animals, viz. :—the jaws, palate, vomer, tongue, branchiæ, and pharynx.—J. H.—P. 22.

“A. b. 325. The stomach of a rat in a healthy state: the cardiac end is covered internally with cuticle; the pyloric is highly vascular and villous: a circular defined line marks the distinction between them.—J. S.—P. 23.

“A. b. 353. The stomach of a full grown goat (*capra hircus*), inflated and dried: this preparation affords an instructive example of a truly ruminating stomach; all the cavities and apertures are shown.—J. S.—P. 24.

“A. b. 354. The stomach of a foetal calf inflated and varnished (*bos taurus*): the preparation shows the groove which at this period of life leads from the œsophagus to the fourth or digestive stomach, for the direct conveyance of the milk into that cavity.—J. H.—P. 25.

“A. b. 437. The crop of an old pigeon taken a few days after the young which it hatched had escaped from their shells: by a comparison with the other (No. 436), it may be seen that the walls have become thick, and the glands enlarged: the secretion from the glands, when first examined, was in such abundance as to fill the crop: it resembles the curd of milk, and is given as food to the young pigeon while still tender, and unable to digest seeds. In preparation 438, this nutritious matter is shown transferred into the crop of the young animal.—J. H.—P. 28.

“A. b. 621. The posterior half of a leech which lived and moved for a period of ten months after being separated from the anterior part of the body. The animal after abstract-

ing blood from a patient was accidentally broken into two during the process of emptying the stomach of the engorged blood; the posterior half being found alive, after some days, in the basin into which it had been accidentally thrown, it was taken up and preserved carefully in a glass of water; for some time the water became tinged with the blood which oozed from its lacerated body, but by degrees a perfect cicatrisation was accomplished, without leaving a trace of the smallest aperture by which either nutriment could have been imbibed or fluids discharged; and, nevertheless, the nutrition and powers of motion of the animal continued in perfect and full operation. It increased considerably in size, and moved about the cicatrised extremity of its body with great agility in water while sticking by the sucker of its tail to the inside of the glass in which it was preserved. This leech was given to me by Mr. Roche shortly after the accident which deprived one half of its body of life, and was preserved in my possession during the remainder of its demi-existence. Its death arose from neglect in not changing sufficiently often the water.—J. H.—P. 35.

“A. c. 741. The cœcum of a rabbit (*cuniculus lepus*), dried and cut open, to show the beautiful spiral valve which winds along its cavity from one end to the other.—J. S.—P. 40.

“B. b. 226. The heart of a chameleon (*lacerta chameleon*). The heart is composed of two auricles and one ventricle. The auricles are large and placed at the upper part of the ventricles; and to the side of each a large sinus is connected which receives the blood of the body and tongue; the two veins which return the blood from the erectile tongue discharge it directly into this peculiar reservoir when suddenly abstracted from the organ during the subsidence of that congestion by which its elongation, and protusion in catching insects, is accomplished. The ventricle is triangular and muscular. The lungs are two in number, and extend on each side from the neck to the sacrum; the cells of which they are formed are polygonal; they are small near the neck, gradually become larger towards the middle of the lung, and at the posterior end have almost disappeared in the formation of one large membranous vesicle.—J. H.—P. 72.

“B. b. 231. The heart of a frog-fish (*lophius piscatorius*). This preparation gives an accurate notion of the construction of the heart in fish. There is a single auricle and single ventricle whose sole use is that of propelling the corporeal venous blood into the lungs, to be rendered arterial by the influence of the water in which these organs are naturally immersed. The auricle is situated on the dorsal side of the ventricle, is of a square shape, muscular in structure, and much fasciculated on its internal surface. At its back part the common opening from the veins, guarded by a double semilunar valve, may be

seen; and anteriorly the passage which conducts the blood into the ventricle is exhibited. This passage is wide, and furnished with two semilunar valves, which give the opening a slit-like form. The mechanism of this valve is demonstrated very plainly in the preparation. The ventricle forms an irregular square; its fleshy structure is vastly more abundant than that of the auricle; it is smooth on the external surface, and presents many fleshy columns internally. Nearly in the centre of its dorsal wall, the opening leading from the auricle is placed; that which forms the mouth of the pulmonary artery is situated at its anterior border. The commencement of the pulmonary artery is surrounded by a thick muscular structure of a pyramidal shape, termed the pedicle; the internal surface of the pedicle exhibits numerous muscular fasciculi arranged in a longitudinal direction; three continuous semilunar valves guard the opening leading from the ventricle into the pedicle of the pulmonary artery.—J. H.—P. 74.

“B. b. 274. The heart of a crab (*cancer mænas*). It consists of a single ventricle without auricles for receiving the blood from the bronchial veins, and propelling it through the arterial system into the body. It is a simple systematic heart, analogous in office to the systematic compartments in mammalia and birds. In its cavity, which is laid open, numerous columns of muscular fibres may be seen crossing and mixing with each other in every direction.—J. H.—P. 78.

“B. c. 335. This preparation shows irregularities in both the right thyroid arteries. The inferior thyroid takes origin from the arteria innominata and runs up to the thyroid gland, lying in its ascent on the anterior part of the trachea, and where it must have been wounded had the operation of tracheotomy been performed on the individual the subject of such irregularity. The superior thyroid arises as usual from the external carotid, but crosses the centre of the crico-thyroid membrane, lying precisely on the spot where the knife is introduced in laryngotomy.—J. H.—P. 80.

“B. c. 342. A successful injection of the arteries and veins of the hand with quicksilver. The capillaries of the surface are shown to great advantage; the tops of the fingers, especially under the nails, are completely covered with small convoluted vessels, and all the large sub-cutaneous trunks are fully distended with the quicksilver.

“The hand of a young emaciated subject is the best fitted for making a preparation of this kind. This following will be found a satisfactory mode of proceeding. A very tight ligature should be bound around the fore-arm a little below the wrist, with compresses under it before and behind on the interosseous spaces, for the purpose of stopping up completely all passage through the vessels; a tube, capable of holding a considerable column of quicksilver, should then be

introduced and secured in the radial artery below the ligature, with the least possible injury to any of the small vessels. The quicksilver is now to be poured into the tube, held slantingly, when it will flow with great rapidity and fill every artery and vein in the hand; the injection may be known to have succeeded when the veins on the dorsum appear moderately filled. Hot water should now be poured on the hand so as to loosen the cuticle and nails, which are to be carefully scraped off, in order that the subsequent drying of the cutis and the exhibition of the subcutaneous vessels may be complete. The hand should now be exposed to a current of dry air, with the tube still in the radial artery, as it may be necessary from time to time to add a little more quicksilver in case any of the vessels appear empty, which may be readily ascertained in the progress of drying, as the vessels become every day more and more visible. As soon as the hand is completely dry, amputation of it may be performed above the wrist in the site of the ligature, and a cement applied to the cut surface to prevent the exudation of quicksilver, which will be likely to occur from the cancellated extremities of the bones or some small openings in their vicinity. Sealing-wax is a convenient cement, and will sufficiently answer the purpose. The whole is now to be immersed in clear spirits of turpentine, by the operation of which the dried flesh is not only preserved but rendered transparent, and the quicksilver in the vessels made to appear of a brilliant yellow colour, altogether making one of the most beautiful and instructive exhibitions of vascular anastomosis that the anatomist is capable of producing.—J. H.—P. 81.

“D. a. 104. The brain of a dog-fish (*squalus caniculus*) in situ. The preparation shows the small size of the brain in comparison with that of the cranium in which it is lodged; the pia mater is well marked, and surrounds the brain closely; the place of the arachnoid membrane is occupied by a glairy gelatinous liquor, which is present in great abundance, filling all parts of the cavity unoccupied by cerebral matter; the dura mater lines the interior of the skull.—J. H.—P. 105.

“F. c. 310. A rare form of human placenta. It consists of two separate and nearly equal parts which were connected to the opposite sides of the uterus, and the vessels of which, after a course of three inches, joined into one chord for the nutrition of a single foetus. The preparation was presented by the late Dr. Tukey.—J. H.—P. 139.

“G. a. 3. A perfect double foetus. There are two heads, two sets of limbs, and two bodies united, face to face, by the heart. The heart is common to both, the aorta gives branches equally to both, and the veins from both enter into the same auricle. One diaphragm serves for both. The preparation is

very old, and its history unknown.—J. S.—P. 147.

This is a work we would recommend the council of every medical or philosophical institution to purchase, its price is *exceedingly low*, and it contains a description, as is obvious from the extracts we have given, not only of the preparations in the Dublin College Museum, but it tells what preparations are necessary to illustrate animal mechanism in its simplicity and its complications. Not only to these bodies would we restrict it, but recommend it to every surgeon who feels any interest in anatomical research. The production reflects great credit on Dr. Houston; if this had been his first and only one it would have alone stamped him as a philosophical anatomist.

FOREIGN MEDICAL LITERATURE.

REVIEW OF THE GERMAN JOURNALS.

Extraordinary Case of St. Vitus's Dance—Poisoning by Ammonia—Remarks on the Mechanism of Labour—Spheno-siphon, an Instrument for Incipient Labour—Curious Case of Abortion.

FANNY CHRISTENS, aged about fourteen, is the daughter of healthy parents, and enjoyed good health throughout her infancy. During the course of the Autumn of 1829 she became very ill; every evening, and at the same hour, her extremities were agitated by involuntary motions. After having been under the care of several physicians, she was at length attended by the author of the present detail. Her state and appearance were thus:—She was excessively emaciated; and for more than a year had been subject to convulsive motions from 7 in the morning until 11 at night. Her arms and legs were constantly agitated by quick and brief jerks; her hands were closed; her head in incessant motion; the eyes open and motionless, the pupil scarcely conscious of the light; the muscles of the face did not contract; her respiration was now short, now tranquil, or interrupted by sighing and coughing. Her pulse was slightly accelerated, and the region which extends from the point of the heart to the spleen was affected by the touch. The temperature of her body was natural; the urine abundant; the defecation occurred only every three or four days. She had never voided worms; and her nourishment consisted wholly of liquids, such as milk or mucilaginous drinks. Throughout the whole duration of the access she continued insensible, a circumstance, and the only one which can raise a doubt as to the nature of her malady resembling St. Vitus's dance more than any other affection.

About the middle of January, 1832, great surprise was excited by a noise (proceeding, seemingly, from the bed of the invalid), which resembled that of striking with the back of the hand against the bedstead, or scratching

it with the nails. For a length of time it was believed that the invalid made the noise herself, but on repeatedly raising the coverlid at the moment that belief subsided. Suspicion, however, of some trick on the part of the parents or attendants induced the author of this tract to take every possible means of discovering it. The situation of the bed was frequently changed; the invalid placed on a chair in the middle of the room, or transported into another; still the noises continued, and always seemed to proceed from the objects nearest to her. If seated on a chair, for example, they proceeded from the chair; her lips, meantime, were motionless; neither were the sounds caused by the articulations. Twenty-two physicians of Hamburg unite with the author in testimony of this fact.

It was on the 12th of January that these extraordinary noises commenced; they increased in intensity for some time, then diminished in power, and towards the middle of March ceased altogether. They had never been heard whilst the invalid was sleeping; they often arose, however, during the night, and might be provoked by striking against the bedstead; also, they would keep time to the music of the voice, or to an organ playing in the street. Moreover, these whimsical sounds would change their nature, and seem like the falling of rain, or of drops of water into a decanter, or the harsh grating sound of a saw; at which the invalid would appear frightened, and say, they were making her coffin.

It is, however, beyond question, that she had the power to produce these sounds, for having been one day thwarted in some wish, she exclaimed, "Well, then, you shall have a glorious racket for your pains!" and consequently an intolerable scratching and knocking ensued. Still she would never confess either that she produced the noises or knew how they were produced. One circumstance was very remarkable:—at the approach of a male, even of her own little brother of six years old, the noises increased in intensity; or by pointing the fingers towards the epigastrium; but if thus pointing they were enveloped in silk the sounds immediately ceased. The power of the stethoscope was tried in vain.

Towards the Spring her convulsions became less violent. In August a spontaneous and somewhat abundant salivation ensued; her appetite and sleep returned; and after a residence of some months in the country, her courses commenced, and thus completed the restoration of her health, which has ever since remained perfect.

Case of Poison by Ammonia.

A young lady, twenty years of age, had been suffering some days from diarrhoea, and, on the 17th of November, she ejected her breakfast. Her mother gave her a teaspoonful of a liquid which she believed to be that which had been recommended by a neighbour as a specific in maladies of the heart. The young

lady complained of its detestable taste, but was compelled to swallow it, and scarcely had she done so, when she fell prostrate in excessive agony. It was ammonia she had taken, bought for another purpose, and thus inadvertently given. I arrived within half an hour of the time, and found that she had been taking a great quantity of milk. She was very pale, and her countenance showed her acute sufferings. The tongue, the pharynx, and the mouth were whitish, and covered with blisters. Between three modes of treatment, each having its peculiar advantage, I hesitated:—the evacuation of the poison by emetic—its neutralisation by vinegar diluted with water—and its conversion into liniment by oil. I decided on the last mode of treatment, and administered spoonful after spoonful of Provence oil, and had the satisfaction of seeing, each time, a diminution of pain. I then ordered an emulsion of eight ounces of the oil of almonds with the mucilage of gum Arabic, and a small quantity of laurel water and nitrate of potass; at the same time the patient was to take alternately a mucilaginous drink and a small quantity of vinegar.

Her pulse lowered every instant, but the pains in the abdomen were succeeded by acute præcordial anxiety, and followed by excessive vomiting, whitish, ropy, and smarting to the touch, emitting a penetrating odour like ammoniacal liniment. Upon further examination, the matter evacuated was found to consist of milk, mucus, and ammonia, combined with oil. Warm drinks favoured the vomiting, which at length consisted of pure mucus. To this succeeded evacuation by stool, which caused an acute sensation of smarting in the anus.

By the evening the vomiting and diarrhoea had ceased, but there had been previous shivering with great suffering in the epigastric region; leeches were applied and the other remedies continued. During the night of the 18th the patient suffered much; she complained especially of difficulty in breathing, and of great pain over the whole surface of the œsophagus; her skin was dry. Except the nitrate of potass, the same remedies had been continued. The fever became high towards the following evening, the pulse small and frequent, the oppression excessive. I immediately took twelve ounces of blood from her, and applied a blister to the upper region of the abdomen; this was succeeded by a more tranquil night; but the blister being very painful, I caused it to be dressed with simple cerate. Pulse 85, and the skin moist. She had a good night on the 20th; the following day profuse perspiration, with diminution of the præcordial and epigastric suffering; nothing remained but the pain in the abdomen. After a night less tranquil than the last, her menses came on, being fifteen days before their regular time. From that hour she began to recover rapidly; her pulse descended to 70; the morbid symptoms disappeared successively,

with the exception of two—she could neither speak nor move. Nevertheless, on the 25th she quitted her bed, and soon after completely recovered.

Manceuvres in Parturition.

“*Corporis integritatem sufficit medicus, amissam resiliuit, non recuperandam demulcet, dignus adeo, qui veri sapientis titulo superbiat,*” says Rœderer, in his discourse *De Artis Obstetricæ Præstantiâ*. And, certainly, medicine is an essentially practical art, the sole object of which being the relief of suffering humanity; therefore is it that by the study of the sick alone it can progress, and that the student can be initiated in the healing art; that of midwifery is the most difficult to teach publicly, and there still exists many universities in which there is not a clinic of this kind. This is not the place to enter into details on the subject of such an establishment. Consult rather the memoir of M. Siebold on the establishment of the clinic of midwifery at Berlin in 1829, a memoir which contains every information on the subject. That which the author would here particularly dwell upon, is the course which the professor would take in giving his instructions. The pupil ought to study the woman during her pregnancy, during her delivery, and after it. During pregnancy the touch is the most important point, for however advanced the student may be in medical science, he must often have recourse to the touch to determine a question of diagnostics, insoluble by any other means. But as it is indispensably necessary that the pupil should be enabled during his experiments to give their result to the professor, that his errors, if any, should be corrected, so it is advisable for such purpose, that they should be alone with the woman to be examined, and thus with each pupil. True, this method of proceeding would occupy a great deal of time, but it would be time well bestowed. The rest of the examination should be confided to the pupil who is to deliver the woman, and to digest in writing a complete detail of the matter, with all her former pregnancies, if any. The professor will also enlighten his pupils as to the use of the speculum, and exercise them in the use of the stethoscope in discovering the place of insertion of the placenta.

As soon as the pains come on, recourse should again be had to the touch, and the pupils in turn should examine the state of the vagina and uterus. And here arises a question of great import, in a case of unnatural labour, which of the two ought to officiate, the professor or the pupil? As accoucheurs must be formed and had, the answer seems simple enough; the pupil should take advantage of such a case to improve his science. How is it in the medical and chirurgical schools? A pupil prescribes a medicine, but it is not given until the professor has decided upon its propriety and utility. Again, having operated many times on the dead, the pupil is

required to try his skill on the living, but the professor is at hand with his advice and assistance, and can take his instrument from him if he use it not properly. Far different is the case in the practice of midwifery. Suppose a case of eversion entrusted to a pupil of little intelligence and less skill, how can it be known whether he acts as the difficulties of the case require? And if the professor operate himself, what advantage is that to the pupil? He cannot follow the professor's hand into the uterus; he can, at most, only form an idea of his muscular power, and of the strong contraction of the uterus. The best alternative seems to be to initiate beginners into all cases of difficult labour gradually.

The Spheno-Siphon, a New Instrument to Cause Premature Artificial Delivery.

BY DR. SCHAHENBURG, OF CASSEL.

All the accoucheurs in Europe are at present engaged in considering the subject of premature artificial delivery, called also forced delivery. Opinions are divided; a great number of practitioners prefer encephalotomy. Reissiger has collected seventy-four cases, in which infants have been safely brought into the world by forced delivery; the number may be now increased to two hundred and fifty, or three hundred. Baudelocque, Capuron, Dubois, Gardien, and Sue in France; and Nisbet and Leighton in England, have constantly rejected the proceeding; and Piringier, in a little work, entitled *Tractatus de Partu Præmature Artificiali*. Viennæ, 1826, makes very weighty objections to it.

Of all the methods hitherto employed to provoke premature labour, that of Nægele's is the most conformable to the means used by nature herself, gentle frictions of the abdomen, warm baths, and light titillations of the vagina are the principal modes by which he causes the uterus to contract itself. And they are preferable to the introduction of prepared sponge, or to the rupture of the amnios; this latter process is often impossible when the placenta is attached to the vagina, and the introduction of sponge is sometimes long and difficult. The process employed by Conquest and Hamilton, if not the most gentle, is at least the most expeditious.

The author of this memoir submits to accoucheurs a plan, which has not yet received the sanction of experience, but the innocuity of which, in case of non-success, cannot be doubted. He proposes to employ an instrument, which he names *spheno-siphon*. The length of the barrel of this syringe is four inches and a half, its diameter ten lines, the bore seven lines, the pipe a quarter of an inch at its extremity, which is pierced with two holes, and its diameter is one line, tied tightly round the base of the pipe; the instrument has a bend analogous to that of the vagina's. After having cleared the rectum and the bladder, the abdomen is bandaged sufficiently tight, and the patient is placed on her back.

Guided on the fingers, the pipe is then gently introduced into the neck of the womb, and the piston pressed inward until resistance is felt, it is then screwed, and the instrument fastened to the bandage around the abdomen. The following day the piston is still further advanced inward; and, finally, on the third day it is made to penetrate to the end of the barrel, and consequently the neck of the womb is dilated one inch, the contractions will then begin, if they have not already begun. It is impossible to anticipate any opinion as to the value of this instrument, the idea of which appears to have been taken from the *dilatateur* of Ducamp: experience can alone decide.

Extraordinary Case of Abortion.

A woman, who had already gone through four labours safely, was seized, towards the fourth month of her fifth pregnancy, with a violent pain in the rectum, accompanied with a discharge from the anus of foetid matter, sometimes coming with the excrement, and sometimes not. The pain quickly extended below the pubes, and at length to the inguinal region, on which she could not bear the slightest pressure. Her urine was scarce and acid, and the constipation obstinate, a watery mucus flowed from the genitals, the vagina was dry and burning, and the neck of it a little open. An antiphlogistic treatment caused all these symptoms to disappear, except the pain in the groin, which yielded only to the repeated application of leeches. After a respite of two months the pains of labour came on, and she was delivered of a fœtus of five months, well formed, and presenting no traces of putrefaction. On a careful examination of the fœtus, M. Malin found, under the skin of the left shoulder, a fish bone, half an inch long, and easily recognised as the tail of a small fish; on the upper part of the thigh he found another. During the whole of her pregnancy the woman was in the habit of eating a great deal of fish, and so voraciously as to swallow bones and all; these adhering to the folds of the rectum caused the perforation with suppuration of the recto-vaginal partition, and penetrated thus to the uterus and the fœtus. The woman completely recovered.

PAROCHIAL MEDICAL REMUNERATION.

WE have lately spent a few moments in conning over the Report of the Poor Law Commissioners, and, while so doing, have been not a little surprised at the different degrees of medical remuneration offered by some parishes to their doctors; for instance, the parish of Lenham, in Kent, which contains about 6,523 acres, and 2,197 souls, has no fixed stipend, but the annual expense for medical advice, &c. is about 70*l.*; while at Horsham, a parish of 9,300 acres, and about 5,105 souls, the same amount only is paid to the medical

officer, so that the latter parish, the extent of which is about one-third more than that of the former, and the population more than twice the amount, pays no more to its surgeon than Lenham. This is not a solitary example, it may be paralleled in any part of the country; its source may be readily traced to the vile and infamous system of contracting at so much per head, or taking a parish, as is too often the case, solely with the view of making a practice. At Gamlingay, in Cambridgeshire, the salary is 5*l.*, the extent 4,080 acres, population 1,319; at Pulborough, in Sussex, salary 5*l.* 10*s.*, extent 5,424 acres, population 1,979; at Kirdford, in the same county, which is a much more extensive parish, comprising 16,000 acres, with a population of 1,623 persons, the salary is only 5*l.*, while at Eastbourn, also in Sussex, 5*l.* is paid to the surgeon, the parish have an extent of only 4,597 acres, with a population of 2,726.

ON THE PROPERTIES OF TOBACCO, BY MR. ATKINSON.

THE common prejudice in favour of tobacco is almost coeval with its first introduction into Europe. When the Spaniards conquered Mexico, they found it in use among the inhabitants, but solely as a stupifying medicine, of which the idolatrous priests took advantage in certain circumstances, when, for example, they wished to appear divinely inspired. For this purpose they inhaled the fumes, which threw them into a high degree of mental excitement, and thus favoured the establishment and currency of their impostures. Nicot, a French Ambassador in Portugal, was the first who, about the year 1560, made tobacco into snuff, and presented it to Catherine de Medicis, from whom it got the name of *Poudre de la Reine*, by which it was known. In Persia, the people became so passionately devoted to this pulverised substance, that the sopher felt himself bound to prohibit its use under pain of death, or, at least, the amputation of the noses of the incorrigibles. James the First wrote a fierce book against tobacco*, and the thunders

* This work was published in 1603, and called "Counterblaste to Tobacco," in which the king says, "It is a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs, and in the black stinking fume thereof nearest resembling the horrible Stygian smoke of the pit that is bottomless."

Camden says, Sir Francis Drake introduced tobacco into England in 1585, and it immediately "began to grow into very general use. A great many persons, some from luxury, and others from their health, being wont to draw in the strong-smelling smoke with insatiable greediness through an earthen tube, and then to puff it forth again through their nostrils; so that tobacco taverns (*tabernæ tabaceanæ*)

of the Vatican were hurled against its pernicious use. These fulminations and prohibitions, however, do not seem to have had any other effect than stimulating the people to a more copious employment of the drug. My French friend recommends the fumes strongly in asphyxia from submersion, but few would wish to qualify themselves in this way for the full benefit it would then produce. Tobacco is distinguished by a pungent, bitter, and acrid taste, no great recommendation to popular favour. But those who want an excuse for smoking, allege that it acts pleasantly on the bowels, relieves dyspepsia, and is an agreeable substitute for pills and draughts. Dram-drinking might be as easily defended. Drams are, perhaps, not more pernicious. Those who, as the poet sings—

Exhale mundungus, ill-perfuming scent,
diffuse generally a filthier odour around them than the bibbers of cordials. Many, indeed, have had recourse to snuff to disguise some other effluvia, as garlic is understood to take off the smell of onions. In these matters, however, *de gustibus non est disputandum*, and there may be no great danger in a man smoking "to the top of his bent," only let it be known that it is a gratuitous indulgence, a thing of choice, and unwarranted by any existing necessity. Nasty things may be fashionable as well as sweet ones, and a filthy enjoyment may be mistaken for one of elegance and propriety. The author before me, who inveighs thus vituperatively against this "*coutume mauvaise*," declares that he has the good of his fellow-creatures at heart, and believes tobacco to be a most pernicious drug. He therefore dissuades them from using it, either at convivial parties or quietly at home, whether in the form of smoke, quid, or snuff, since it has no medicinal power upon the organs of the amateur whatever. Imagination assuredly goes a great way in every thing, and even tobacco has its supporters. But the smoker, whether of pipe, hookah, or cigar, may be induced to consider that nervous irritability and febrile inconvenience very often close the fumigating career, and he may at last think proper to pause before he injures the important function of his system irrecoverably. "Blind mortals!" says my emphatic friend, "know ye not that the drug which stupifies the senses, affects the muscular fibre, and produces a sedative effect, nervousness, stupidity, inanition, paralysis, and, finally, death."—*India Journal of Medical Sciences.*

are now as generally kept in all our towns as wine-houses or beer-houses."

It appears from a note in the "Criminal Trials," vol. i. p. 361, that in 1600 the French Ambassador, in his despatches, represented the peers, on the trial of the Earl of Essex and Southampton, as smoking tobacco copiously, while they deliberated on their verdict.

Reports of Societies.

MEDICO-BOTANICAL SOCIETY.

February 24th, 1835.

Dr. CHOWNE, M.D., in the Chair.

Dr. E. D. MORRIS, F.R.S.E., and F.C.P.E., was admitted a Fellow of the Society.

In accordance with the announcement at the last meeting of this Society, Mr. Hanham explained the manner in which he prepared his Herbaria. The process was exceedingly simple:—the plant to be preserved must be perfectly fresh; the under surface of the leaves is covered with mucilage, and applied to the paper, to which it is caused to adhere by moderate pressure. The mucilage must be very pure and fresh; no chemical means are employed.

Mr. Everitt, the Professor of Chemistry, previous to entering on the subject (Atropine) he had allotted for this evening's lecture, made a few remarks on the preservation of plants in gases. Humboldt had stated, that plants which were put into any gas would vegetate fungi, but Mr. Everitt had in his possession, and exhibited to the Society, vegetables which had been in bottle seven or eight years retaining their natural form and flexibility, and in a proper state for the knife of the dissector: he considered, therefore, that this plan of preserving vegetable specimens would be especially available in those cases where it is desirable to submit rare plants to the eye of the experienced and scientific botanist. The specimens exhibited were preserved severally in the vapour of alcohol and of æther, in hydrogen, nitrogen, and in carbonic acid gas.

Mr. Everitt then mentioned that the specimen of Atropine which had been transmitted to the Society by Earl Stanhope from Professor Geiger, was not large enough for him to try experiments with, and he must therefore be contented with translating the observations of the Professor. It was discovered by Mein, Geiger, and Hesse: it exists on all parts of the *Atropa Belladonna*, but is principally obtained from the fresh dried root. The Atropine (of which a specimen was sent round) crystallises in white, transparent, silky, vesicular prisms; is heavier than water, and remains unaltered by the air. It does not possess any odour, but if it be at all impure, there is an evident difference in the crystals, and it has an highly offensive smell like that of hyoscyamine or daturine. The taste of the atropine is offensively bitter, giving a tingling sensation with a metallic after taste. It is highly poisonous, causing contractions of the œsophagus, with dryness of the mouth, vertigo, and headache, followed by dilatation of the pupils. It is stronger than either hyoscyamine or daturine; one thousandth part will affect the pupil, and a larger quantity will dilate it for ten or twelve minutes. In two cats to whom it was administered it produced champing and frothing at the mouth, with convulsive action of the head, previous to its exerting its influence

on the pupil. It has an alkaline reaction on vegetable colours, and the effect is not evanescent. It melts at the temperature of 212°. When the heat is higher, it becomes partly decomposed and partly volatilised. The celebrated German chemist, Liebig, has carefully analysed it, and gives the following as its composition:—7.83 hydrogen, 70.98 carbon, 4.85 nitrogen, and 16.36 oxygen. It is apt to undergo spontaneous decomposition, which is much facilitated by an elevated temperature and the presence of moisture. It is readily acted on by acids and alkalis. Two hundred parts of cold, and fifty-four of hot, water dissolve one part of atropine. Although there is such a disproportion in the quantity dissolved by the hot menstruum, the salt is not precipitated when the solvent has cooled. The finest crystals of this salt are obtained by boiling it in water at 212° for a long time, when thirty parts of the liquid will take up one of the salt, the surplus being deposited crystallising beautifully as the water cools. It has not any affinity for the fixed organic alkalis; the addition of tincture of iodine causes a yellow colour. If the infusion of galls, or gallic acid, be added to a moderately concentrated solution of atropine, a curious result takes place,—the fluid becomes gelatinous; and even when the solution of the salt is considerably diluted, a jelly-like deposit occurs. It may be observed, that those substances which exert such chemical action on the poison generally serve as antidotes, and it may be exemplified by the effects of albumen on the bi-chloride of mercury. Professor Thenard took a solution of the oxy-muriate of mercury by mistake for eau sucrée; he immediately had recourse to the white of eggs, and his life was saved.

Alcohol is a ready solvent of atropine; an ounce and a half of the spirit will dissolve an ounce of the salt, but, notwithstanding, crystals cannot be obtained by evaporating the spirit, the residue being an uncrystallisable, gelatinous mass; water is the best solvent, when it is desirable to obtain crystals. Æther is a much worse medium for its solution; twenty-five parts of cold and six of hot sulphuric æther will dissolve one part only of atropine.

The mode of preparing this salt according to Professor Geiger is extremely complicated, and it would answer no good purpose to go into it at length. If the leaves of the *atropa belladonna* are employed, great difficulty will be experienced in getting rid of the colouring matter, indeed this forms one of the difficulties in obtaining all proximate principles; it will be obviated or, at least, lessened by using the fresh-dried root, coarsely powdered. This is exhausted by strong spirit, containing at least 90 per cent. of real alcohol; to this alcoholic solution or tincture hydrate of potash is added, and the mixture filtered, and saturated with sulphuric acid; half the spirit is then to be distilled off, and these processes of filtration, distillation, and precipitation, are to be repeated five or six times, until the salt is obtained pure. All this is to be carried on

with great despatch, and without too much heat, as the atropine is very liable to be decomposed.

The salt unites with acids and alkalis, but the compound bodies thus formed have not yet been sufficiently examined, for an accurate opinion to be given concerning their properties.

It was announced that at the next meeting a paper by Dr. Hamilton, of Plymouth, on some Mexican plants, would be read.

There were on the table various articles of the *materia medica* belonging to Mr. Battley, on which Dr. Sigmond made some observations. There were fine specimens of the colocynt, squill, opium, aloes, calumba, cardamoms, cantharis, camphor, colchicum, conium, castor, rheum, cinchona, sarsaparilla, cinnamon, cassia, ipecacuana, gum ammoniacum in mass and in tears, belladonna, aconitum, and finally the physic nut of Africa, with a specimen of its expressed oil. The value of this exhibition was much enhanced by the addition of specimens of the same drugs as they are commonly met with in commerce; the great difference between the two was very perceptible, and would of itself constitute a most cogent reason for a revival of the laws concerning the drug trade, and indicate most strongly the necessity of placing druggists under the superintendence of properly qualified individuals. When speaking about the specimens of opium on the table, Dr. Sigmond took occasion to allude to the adulterations to which it is liable, and mentioned that it is not unfrequently mixed with *cow dung*. He added that he had been informed by Mr. Horne, that, having occasion for some powdered opium to prepare the acetum opii sedativum, he procured some at a respectable house, but found it almost inert, and, on examination, he ascertained that the acetate of morphia had been previously removed. The African physic-nut was stated to be obtained from the *Jatropha Curcas*, a tree of the natural order Euphorbiacæ; it is considered a purgative in the dose of a nut and a half. Dr. Morris stated that it acted equally in the form of emulsion.

COLLEGE OF PHYSICIANS.—In answer to a question from Mr. Wakley, the Chancellor of the Exchequer replied "that he had not received the regulations of the College of Physicians, to which he had adverted on a former day, but he expected they would be sanctioned. In order to become a licentiate, it was necessary to have a university degree, and to have resided a certain time at a university. The course intended to be pursued for the future, he believed, was to dispense with a residence at a university, and to have a certain form of examination, and a certain attendance at medical schools. Any person who should, therefore, pass his examination would be at liberty to act as a licentiate. Those, therefore, who might study at the universities would, in future, have no advantage over any other who might be competent to pass an examination.

THE

London Medical and Surgical Journal.

Saturday, March 7, 1835.

REMARKS ON THE DISUNION AMONG
MEDICAL PRACTITIONERS.

IN these times, when the cordial union of all ranks of medical practitioners is so desirable, and even essential to gain their just rights, if there is one subject more calculated than another to rouse the interest and arrest the attention of medical men, in whatever branch of the profession they practise, it is the low state of mutual courtesy and union among them. Professors of an enlightened science, the object of which is to distribute that blessing, which is beyond price, to mankind, to alleviate disease, and combat its Prorean inflictions of pain and anguish; nevertheless, we are found too frequently at variance each with the other, and expressing our mutual dissent, with respect to professional views, with a rancour and virulence (particularly some of our Journals) one should think better fitted to any other than that profession which consults so much the happiness and welfare of society.

To such as are not engaged in the profession, or initiated in the mysteries and miseries with which it is conversant, who look on it as a career of honourable exertion, calculated to awaken the finer feelings of our nature, and give birth to the most refined sentiments, it must appear in the last degree strange, that generous emulation and liberality of conduct are not so frequently the accompaniments of medical rivalry as envy and asperity. That to the many of us it seems easier to denounce than to applaud, more congenial, to borrow a metaphor from our own art, to wound than to heal, a brother practitioner.

In private practice, we much fear that the feelings, to which we have alluded, too often sully and spot the polished surface we should, as the curators of their health, present to those, who narrowly watch our movements and weigh our motives, and are prepared to measure out a severe criticism on them when detected to be of a selfish and ungenerous character, such as to stain the inward uprightness and kindly policy which it behoves us to exercise towards each other, and which in the end would be most beneficial. That there are many highly honourable exceptions to this general imputation must be confessed, but enough, and too much, of acrimony exists among us to poison our social intercourse, hold us up to public animadversion, and warrant the few observations on the subject which we are about to lay before our readers.

As the light of comparison often pierces the cloud, which another mode of appealing to the reason might in vain essay to penetrate, we may, in passing, be permitted to say a few words on the treatment of each other found among those following the professions ranking immediately above ours. Looking at the clergy, cultivating an analogous but infinitely more sublime function, we perceive that their reciprocal habits are marked throughout by a kindness and urbanity, which allow not of petty carping and personal vituperation. They may, they do, differ among themselves; orthodox may clash with evangelical, but their expression of dissent does not descend into coarseness, or individual invective (at least, if such happen now and then, it is but an exception to the general rule, and discountenanced). Their disputes are argued without rudely violating the amenities of social life, and a classical halo is shed over the whole, which we should rejoice

to see communicating some portion of its lustre to our kindred science. This liberality, this absence of personal strife, arises, it is fair to presume, in a certain measure, from the forbearance inculcated by their sacred function; but we must be permitted to add, that in no less a degree does it spring from those habits of reflection and self-command, which a well disciplined and liberal education induces. We would not, however, here, we repeat it, be understood to imply that there are not many, indeed a numerous portion, of the medical profession, who possess a fair average education, and many of them a superior acquaintance with classic lore, but **THEY** are not the majority to whom these strictures are addressed and applied. Nor let these, forming the mass of our body as they do, take umbrage at what we now, bound by a love of truth, say, for among them there is valuable mental ore, though unwashed and unfiltered,—there are intellectual gems, rough and deficient of splendour, only because they have not undergone the metamorphosing hand of the artisan,—there are minds which shine forth, darkened and eclipsed only from the want of a liberal education.

Let us now descend a step on the ladder of professions: we shall behold the lawyers, though at apparent issue, in actual concert. The *esprit de corps* animates them, and their differences of opinion, although openly expressed, allude not, except in rare instances, to the *personal* talent, or capability, of their antagonist; and even when they adopt this course their language does not plunge into the mire of scurrility. Their declamation, though loud, (and who has not heard it?) is employed in arguing and dissecting the matter, not the manner or accidental circumstances of their opponent. Their writers are not in arms against each other, and against the repu-

tation and respectability of their profession. Their pleaders, though engaged in warm debate, pay that homage to public opinion, and courtesy one to another, which prevent the miserable system of reviling and *personal* abuse, which seems to have blinded and led captive, in numerous instances, disputants on medical subjects. Inferior practitioners in the law do not endeavour to stultify their calling before the public, they reflect that

“ Corsaires contre corsaires
Ne font pas leurs affaires,”

and eschew that acerbity of contradiction in their professional collisions, which often signalises the less wary cultivators of physic. Among the lawyers there are no periodicals, which, under the pretence of recording the passing events happening in their body, seize upon them for the purpose of maligning private character, or making them a stepping-stone, whence to spring from what concerns the furtherance of science to what is personally abusive, can answer no other end than the gratification of bad passions and worse principles.

The examples afforded by professors of divinity, or law, then, have not taught us to wage a fratricidal warfare,—have not put into the hands of some of our Journalists the envenomed shaft, wherewith to stab private fame, or deal a coward blow at the back which is turned,—have not taught them to use the rhetoric of Billingsgate, and, in their controversies and remarks, to brandish the *oyster-knife* of criticism instead of its keen-edged razor, or to inflict (our brethren of the *Lancet* will understand us) a *contused*, in preference to an *incised*, wound. No! some other fountain, whence the evil hath run its muddy course, must be sought.

Scandal has a deep well, and too many

among us unfortunately love to draw her bitter waters mantling with the defects of our neighbours, but this frailty *we* participate in common with the rest of mankind. We must go farther to seek the *especial* cause of our jarring state. We need not go far. Folly and ignorance, individual interest, and sordid gain, lift up their heads, and extend their claws to gripe the lion's share in our squabbles. Again we repeat, the want of that education which fertilises the brain and softens the manners, *has been* more egregiously wanting among us than in any other profession. “ *Hinc illæ lachrymæ.*” Hence the divisions and subdivisions, the jealousies, the petty cavillings disturbing the harmony of our medical camp. Hence its would-be champions, and self-constituted instructors, wielding the medical press, presume on the lack of intelligence among the many, and violate justice too often with impunity, deeming the breadth of a hair a sufficient boundary between them and a breach of the law. The non-medical press, on the other hand, viewing these assaults on private character mingled with matter professing other and more praiseworthy objects, and astonished at our eternal bickerings, which have even become proverbial, considers us beneath its notice, and sets us down as a body unilluminated with a soul. And this silent contempt we undergo because we *will not* agree together, because each surveys his neighbour with an eye of hostile rivalry, not of liberal competition, because each is ready to assail and criticise, instead of treating with tenderness, his fellow practitioners' motives and conduct.

Is this a state of things which should be allowed to exist longer among men skilled in their profession, dealing out each day of their lives an immense amount of good to the community they serve—

aye, and serve as no other description of benefactors do? for who gratuitously gives away the sweat of his brow and brain—who toils in the work of charity like the medical practitioner? Who confers such solid but unpaid-for benefits upon the public? or where shall we search for a parallel to his unremunerated labour? Will the lawyer forego his fee, or the schoolmaster teach for nothing? Will the tradesman part with his goods, or even Holy Mother Church grant her blessing, be it at christening or funeral, without demanding an equivalent?—No! they each and all require the stimulus of gain; and our body stands alone, proudly and honourably in this respect. We are, without a figure, the Samaritans who go about doing good where hope of reward—at least on earth—there is none, or it is indefinitely distant. And shall we, who are capable of and perform these works, worthy of the gratitude of all around us, erect the standard of intestine warfare, and encourage an undermining schism within ourselves? Shall we, deserving of the admiration and respect of society, to which we render such signal and unrequited services, provoke its contempt by insanelly setting our faces against and harassing each other? Forbid it, common sense! forbid it, that policy, which should join within the links of amity those who are embarked in the same cause! Let us hope that better things are on the eve of completion, that a nobler spirit of mutual feeling is about to animate us, and convert that rope of sand, which now deceitfully encircles, into a chain of lasting force to bind us together.

One word more with respect to those detestable attacks upon private character, which in every honest mind can excite no other feeling but indignation and abhorrence: we shall ever, as we have hitherto

done, repudiate them. If the shaft of ridicule—and heavy disputes are often best settled by it—must be sped to effect a worthy purpose, we guarantee that its head shall be pointed and sharpened by skilful hands. No archer of our corps shall take a bungling aim, or pierce the person where the opinion is the object; and when opinions must be attacked, they shall be met openly and fairly, and the matter be one of intellectual, not personal, conflict. Once for all, then, we wipe our pen of all personalities, unless egregiously provoked and pressed by the law of retaliation, and promise to conduct our Journal, so that we may say,—*Hic murus aheneus esto, nil conscire sibi, nulla pallescere culpa.*

GIN PALACES AND THEIR BANEFUL EFFECTS.

“Salus populi suprema lex.”

On Tuesday evening in the House of Commons Sir J. Beckett presented a petition from certain inhabitants of Leeds, praying for the further consideration of the legislature with respect to these superbiest pests. Mr. Baines seconded the prayer, which was further supported by Sir G. Strickland, Mr. Robinson, and Colonel Evans, and finally ordered to be laid on the table.

In looking over these evils, which from time to time lift up their heads to infest society, the acute observer cannot help fixing his attention on those gaudy receptacles for the sale of disguised poisons; very appropriately named gin palaces. Pass through which street he may in any part of the town, his eyes are sure to alight on one of these poison shops, painted and stuccoed in palatial style, bedizened with a flaring lamp, but, like the fabled upas tree, shedding from its rank interior the causes of disease and death to thou-

sands. No one who has not witnessed the crowds which continually resort to worship the leaden-hued demon, who presides within these temples of drunkenness and ruin, can imagine their extent, especially in the working districts. It would appear, from the vast quantities of the fiery composition, nick-named gin, which they dispose of to dram-drinkers of every description, that the appetite of the lower orders for their ancient nut-brown beverage is fast declining, and will be soon totally extinguished by its trashy rival.

Let any body enter one of these showy Pandemoniums, and survey the countenances of the congregation there assembled. The inebriated eye and sallow cheek will meet his view on all sides, proving the magnitude of the evil. At night, more especially, intoxication, having gratified its thirsty propensity, stalks forth primed for violence and ready for crime. Vice and folly hold their court within them, and are rendered trebly vicious and foolish by the copious libations furnished from the vile tubs which, as it were, form the battery of these villainous holds. So thickly are these traps to catch the roaming drunkard interspersed in all directions, that, half reeling and irresolute as he wends his way staggering homewards, at every turn they salute his vision, and break his sober resolves; he takes them in rotation, and finishes his guzzling march by an introduction into the station-house or into a ditch.

Formerly the little humble public houses, which were convenient to certain of his Majesty's lieges for refreshment, presented none of the allurements now blazing forth from their stately rivals; but now, even those finding that their occupation was gone, stolen away, they also metamorphosed their outward modesty, and

adopted the Jezebel front of their painted neighbours. "Othello's occupation's gone," few of the sober looking structures remain; and if a person who had been absent from London for the last ten or fifteen years were now to enter it, he might look in vain for the plain brown-looking brick and mortar surface of his old acquaintances; in lieu of them he would be enlightened with the effigies of a staring, huge-windowed, and lofty edifice, calculated, not for the accommodation of wayfarers, as originally intended, but for their destruction, by the sale of adulterated liquors.

How much the health and morals of the lower classes in the metropolis are deteriorated by the consumption of the stuff vended in these wholesale laboratories of liquid fire, the medical practitioner knows full well. Delirium tremens, indigestion, and an endless train of diseased liver and other viscera, claim this as their cause, while the immense excitement induced by throwing large quantities of ardent spirit, (or some compound which sets analysis at defiance,) into the stomach, leads to results mischievous in the highest degree to morality and decency. Were malt liquor the intoxicating agent, its effects would not be so pernicious. Sleepiness would deaden the active force, and incline to peace instead of outrage.

It will be inquired "is there no remedy for this crying evil?" We fear not, unless people can be persuaded to their own good, sometimes a very difficult thing to accomplish. The Government might, seeing that the proprietors of these splendid Bacchanalia realise vast profit from the concoction and brewing of their commodity, lay upon their backs the whip of taxation a little more heavily. Their licence might be held under a fine, computed with reference to their annual re-

ceipts, instead of according to their rent, which now is the case. It may be urged, that the liquor is sufficiently taxed already, but we answer they have, within their den, a transmuting talisman, which trebles whatever quantity enters it. Let them be taxed accordingly.

In the last Parliament Sir A. Agnew proposed, that the interior of all places for the sale of liquors should be thrown open, so that their orgies being exposed to view the more tender of reputation, and less abandoned bibbers might be restrained, if not reclaimed. We are not, however, of opinion, that this sort of opening medicine would be tolerated in the present times, and therefore earnestly trust that the Government, in their wisdom, will hit upon some plan of abating this growing nuisance, which it needs little acumen to see is

“foul in many a fold,
Voluminous and vast,—a serpent armed
With mortal sting.”

Foreign Medicine.

HÔPITAL DE LA CHARITÉ.

Clinic of M. Corbin.

GENTLEMEN,—Phlegmonous erysipelas is frequently complicated with gangrene, but the latter condition arises in various ways. Mortification of the skin is generally consecutive to destruction of the subcutaneous cellular tissue, and in this case we can detect, before gangrene takes place, some signs of fluctuation, and if the disease be abandoned to its course ulceration occurs, and shreds of the cellular tissue, mingled with pus, are discharged, the external integuments are destroyed, and the muscles or aponeuroses are laid bare. In such instances free incisions, if made at an early period of the disease, may prevent mortification, and, if at a later stage, they may limit its extension. The parts do not assume a black appearance, nor is there any gangrenous odour. In other and less complicated cases, to which alone ought to be applied the term gangrenous erysipelas, the gangrene commences in the skin, and is preceded by the appearance of phlyctenæ, or by the black and livid tint and peculiar odour of

this class of diseases. Here incisions have always appeared useless, and where they have been made, the edges of the wounds suffered more from gangrene than the other parts.

Erysipelas of this last mentioned species is usually very severe; it is characterised from the very commencement by prostration of strength, and is almost always fatal. Such cases are fortunately rare; thus in erysipelas of the limbs, in nine cases out of ten gangrene takes place after the suppuration and destruction of the cellular tissue. We frequently see pure phlegmonous erysipelas arise in the scrotum, and a part of it destroyed by mortification. Upon the face and hairy scalp gangrenous erysipelas (confining the term to its proper limit) is rarely seen; and when it does occur, the skin always mortifies after suppuration of the subcutaneous cellular tissue. This fact is illustrated by the following case, which is also interesting in some other respects.

“A man, forty-eight years of age, having drunk very hard, received a sabre wound, three inches long, upon the left parietal bone. He was admitted the next day into the Hôtel Dieu. Attempts had already been made to promote the immediate reunion of the divided parts, although, from the appearance of the wound, they were not likely to succeed. The adhesive plasters which had been employed were removed, and the lips of the wound were separated; the bone was not exposed, but at the anterior part of the wound, which approached the coronal suture, the fibres of the aponeurosis of the occipito-frontalis muscle were denuded. The edges of the wound were laid very gently together, and, as erysipelas was at that time very common, cold lotions were ordered, and twenty leeches applied to the neck.

“On the 4th, the face was rather swollen.

“5th. Slight erysipelatous appearance on the right eye; cold lotions continued; blister to the neck. The erysipelas continued to extend, but before it had reached its highest degree of severity, it disappeared entirely.

“On the 9th, there was seen at the bottom of the wound a yellow looking substance, which was found to be the aponeurosis already mortified. The patient complained of being dull and heavy; and of a sensation of weight in the head, which was so painful that he could scarcely bear to rest upon his pillow.

“11th. Manifest fluctuation at the back part of the scalp, and extensive separation of the scalp from the bones. The abscess was opened, and a small quantity of pus discharged. Much relief followed, and the following days no remarkable symptoms occurred. Mortification of the aponeurosis still continued, and shreds of yellow looking fibres were from time to time separated from it. The patient still continued drowsy, but could obtain no sound sleep; inflammation of the brain and its membranes, with violent fever, convulsions, and great prostration of strength

soon came on, and the patient sank, and died in a few days.

“ Upon dissection, the lungs were found engorged with blood, and appearances of chronic gastro-enteritic inflammation were detected. Upon the outside and upper part of the cranium, the cellular tissue between the bones and the aponeurosis was entirely destroyed. The surface of the bones was covered with a sanious discharge, and exfoliation of them had commenced. The pia mater was inflamed and thickened, and between this membrane and the arachnoid there was an effusion of pus. This case is remarkable, not only on account of the progress of the erysipelatous inflammation, but it shows, also, that a wound on the head may remain open although the bones are not denuded. If the occipito-frontal aponeurosis is exposed it exfoliates like a tendon, and often in a very gradual manner.

“ Cases of erysipelas are occasionally seen which appear to be intermediate between the superficial and phlegmonous forms of the disease. In such instances there is but little swelling, no collection of matter to any great extent under the skin, but here and there small insulated abscesses. In a patient named Spainvielle, after an attack of erysipelas of the face and scalp, several small abscesses formed in the neck, behind the ears, and upon the cranium. In another patient, after a similar attack, accompanied with enormous swelling of the face and scalp, an abscess formed upon the right upper eyelid, and numerous small collections of matter, from the size of a filbert to that of a cherry-stone, also formed upon the scalp. These abscesses remained for a long time very hard; some of them disappeared spontaneously, and others were opened, and healthy pus was discharged from them.

“ External erysipelas frequently disappears from one part, while at the same time the disease attacks a more or less distant region of the body. Thus, in a man named Tessier, who was admitted into the Hôtel Dieu, erysipelas of the leg and foot disappeared when the face became the seat of the disease, and the parts originally affected were again attacked when the face recovered. Erysipelas also frequently exercises a revulsive influence upon internal diseases. A young man was attacked with acute pulmonary catarrh; he was bled frequently but without decided advantage; he was much oppressed, skin hot, pulse hard and quick. He was attacked with erysipelas of the nose, which quickly extended to the face and scalp. The feverish symptoms increased, and he became delirious; leeches were applied to the neck, and he was bled in the foot. In a few days the erysipelas disappeared. From the time that the external inflammation appeared, and while it lasted, the patient breathed freely; there was less expectoration, and, in fact, there was every reason to believe that the bronchitic affection had ceased. It might at first have been presumed that this diminution of the symptoms depended as much

upon the repeated abstractions of blood as upon any revulsive influence of the external inflammation; but no sooner had the erysipelas ceased than the cough, oppressed breathing, and other indications of bronchitis, reappeared with increased severity, and it was again necessary to have recourse to venesection.

“ Phlegmonous erysipelas of the lower extremities, of the most severe kinds, is very often produced by the slightest external causes, either from excoriations, slight wounds, the neglect of old ulcers, or by applying stimulating remedies to them; and sometimes simple contusions are sufficient to produce the disease; as in a man named Wivel, among other similar instances, who died in three days of erysipelas, in consequence of falling upon his knee. Sometimes no external cause can be detected.

“ When we oppose to these cases numerous instances of other patients placed in the same circumstances, or even affected during the same season with much more severe external lesions; and in whom, notwithstanding, no erysipelatous disease is developed, we must presume that, in the former there existed some peculiar disposition, or, to speak less vaguely, a lesion of some important organ, and particularly of the abdominal viscera. The idea is confirmed when we detect a red and dry tongue, headach, sensibility in the epigastrium, an inflated state of the belly, diarrhoea, or enlargement of the liver; but the results of dissection in eleven fatal cases of erysipelas affords the most satisfactory proof of the accuracy of this opinion.

“ In the first, a patient named Tupin, the mucous membrane of the stomach was nearly of a black colour, and softened throughout the region of the pylorus: the commencement of the duodenum exhibited the same appearances. Almost the whole of the small intestines, to within an inch above the cæcum, was of a deep violet colour. In the large intestines, some of the glands were hypertrophied, and appeared like small pustules.

“ In the second case (a patient named Plüg), the stomach was highly coloured in different parts, with patches of a red and brown appearance; the colon, throughout its whole extent, of a deep red colour.

“ Case 3rd. Duranton: appearances of chronic inflammation of the stomach and duodenum, characterised by reddish tubercles; rectum distended with fæces.

“ Case 4th. Leerbier: peritoneum of a red colour, with serum. Stomach, patches of brown and black colour. Duodenum, a circular ulceration about the size of half-a-crown.

“ Case 5th. Schier: mucous membrane of the stomach softened, and of a dark slate colour; the submucous cellular tissue of the duodenum deeply injected; red patches in the cæcum.

“ Case 6th. Wivel: the mucous membrane of the stomach and duodenum softened, and of a grey colour throughout nearly its whole extent.

“Case 7th. Debry: In the stomach, near the cardiac orifice, was found a smooth hollow tumour, the size of a small rennet apple, containing bloody serum. The whole surface of the stomach of a dark colour.

“Case 8th. Tronnet: the mucous membrane of the stomach softened, and generally pale; small red spots on the great curvature.

“Case 9th. Lefebvre: liver studded with grey tubercles; spleen softened, and of a large size.

Case 10th. Lambert: the mucous membrane of the stomach of a deep slate colour.

“Case 11th. Delgatta: Biliary calculi were found.

“Thus, with the exception of the last two cases, in which no striking morbid appearances were detected, in all the bodies there were considerable lesions of the abdominal organs. If we compare these results with our observations during life, it will be difficult to deny that most cases of erysipelas depend upon some internal cause. If such be the most frequent cause of erysipelatous diseases, it may appear singular to attribute to these maladies a decided influence over the progress of internal inflammations. This influence is, however, very evident, and not more astonishing than other revulsions effected by nature or art. No fact is better ascertained than this kind of antagonism, which is established, in certain cases, between the skin and internal mucous membranes, and especially the gastrointestinal; hence the use of purgatives and emetics in the treatment of erysipelas. But these means should only be employed when the digestive powers are healthy, or at least when there is simple obstruction of the stomach and bowels. In similar instances to those above described, we must, it is true, act principally upon the abdominal organs, but antiphlogistic and emollient remedies can alone be employed with safety.”

Sketch of the Subjects of the two Prizes offered by the Société de Pharmacie, at Paris.

AMONG the substances belonging to the organic kingdom, starch is, without contradiction, one of those which have induced the greatest number of experiments. This substance, so abundant in nature, constitutes, as is well known, the alimentary principle of a great number of vegetables.

It also supplies us with various products by the modifications it undergoes, which daily appear to be assuming greater importance, and one of the most remarkable of these is sugar, which it can form by several processes; this sugar has been the subject of great labour and application for several years, but the causes of its formation are, as yet, obscure, and a great deal must yet be done to enlighten us on that subject.

In order to arrive at this end, the Society of Pharmacy proposes to chemists the questions which will be soon stated.

It would be too long, and *malapropos*, to give here a sketch of the chemical and microscopic operations which have been undertaken in order to demonstrate the structure of starch, or to make known its nature, and the different modifications it undergoes in passing to the state of gum and of saccharine matter.

When Kirckhoff discovered the remarkable property of the saccharification of starch by the intervention of sulphuric acid and water, he extended his experiments to other bodies, and he recognised the existence of a similar property in gluten, but all endeavours to explain this saccharine change were almost useless.

The experiments of Kirckhoff on the reaction of gluten and starch tend to make us presume that, in the germination of the cerealia, sugar is formed at the expense of this substance; nevertheless this hypothesis will not explain what takes place when, in order to convert fecula into alcohol, fermentation is produced by adding malt. These considerations induced M. Dubrunfaret to examine this question carefully, and, in an excellent essay, approved by the Central Society of Agriculture in 1823, he arrived at this conclusion, that malt acts on starch by reason of a particular property which the other cerealia have not, or only in a much less degree.

He endeavoured to discover to what principle this property belonged; he attributed it at first to hordeine, then to a matter which he called *soluble gluten*, and was thus the first to recognise that in malt the property of causing fermentation belongs to a substance soluble in water. It must be acknowledged that this explanation of the functions of malt with regard to starch, still leaves room for inquiry.

Latterly the labours of Messrs. Payen and Persoz have thrown considerable light upon this question; these chemists have extracted from malt a substance which they have found to possess the property of converting the amyaceous fecula into sugar, and they have given it the name of *diastase*; they state that this substance exists in the seeds of barley, wheat, &c., near the germs and not in the radicles, and that it is also found in potatoes after their germination, and near their points of insertion.

It is generally accompanied in these substances by an azotic matter, little soluble in water, and insoluble in alcohol, but coagulable at a temperature of from 65° to 75°. The matter to which they have given the name of *diastase*, is white, solid, amorphous, insoluble in concentrated alcohol, soluble in water and weak alcohol; it has not any peculiar taste, is neutral, but, if moist, will soon become acid on contact with water; it throws down a white precipitate with the subacetate of lead; when brought into contact with fecula at the temperature of from 65° to 76°, it rapidly detaches what are called the integuments, and soon offers a substance which has the appearance of gum, and constitutes *dextrine*.

If the action of heat be continued a long while, but always within the limits mentioned, a saccharine matter is obtained, capable of fermentation, analogous to that produced by sulphuric acid according to the process of Kirckhoff, except that the saccharification appears to be only partial, and is scarcely more than a fourth or a third of the weight of the starch; let us add, also, that temperature has great influence on this property of the diastase, for when heated to ebullition it has not any influence on the fecula.

The action of the diastase is certainly the more remarkable, since the smallest quantity suffices to act very rapidly on the amylaceous fecula; 1-2000th part, for instance, added to a thick solution of starch, heated to from 65° to 70°, will render the latter fluid, and change it successively into a kind of gum, and sugar.

To what is this energetic action to be attributed? Messrs. Payen and Persoz assign to the diastase only a kind of mechanic action, saying that, under the influence of water, it alters the order of the elements of the internal parts in the fecula, produces two soluble substances, and then favours their escape from the integument.

We may thus perceive that, although the substance in malt which acts on the amylaceous fecula is now known, nothing positive has yet been ascertained in regard to the explanation of the facts, for we are yet ignorant of the real nature of the diastase, and upon what principles in the starch it exerts its action. We are also ignorant if the diastase is a pure immediate principle, or the result of a reunion of complex bodies. These are the questions that, in the actual state of our knowledge, we have a right to propose, consequently, with due regard to the importance of the subject, as well as in a scientific point of view, as also its uses and applications, the Society proposes the following questions.

1st. What is the chemical nature of the diastase?

2nd. How does it act on starch in the modifications it produces?

The prize will be a gold medal of the value of 1,500 francs.

Second Subject for a Prize.

The analysis of an organic substance ought not to be confined to the separation of some insignificant salts, and gummy, extractive, and resinous matters, often very complicated; we must, when the substance will allow it, seek for those crystallisable, or, at least, pure principles, on which the most remarkable properties of the vegetable under analysis depend. The application of several of those already discovered in therapeutics, has been too successful not to induce us to seek in vegetables, acknowledged to be active, the causes of their actions on the animal economy. There are also some principles which do not appear to have previous existence, and which are only the result of the reaction of agents employed

for their extraction; in the actual condition of organic chemistry this is a point which the chemist ought to examine, in order to explain the causes of the formation of these new products.

Among the vegetable substances, the action of which is not doubtful, may be cited the foxglove (*digitalis purpurea*). Notwithstanding the experiments on this plant by Dulong d'Astafort, Haase, Planizza, Leroyer de Genève, Pauquy, and, recently, by Welding, there is much obscurity as to the real nature of the principle to which the properties of the digitalis are to be attributed. In order to ascertain definitively if there be a similar principle in existence, the Society proposes a prize of 500 francs for the essay which solves the following question:—

“Does there exist in the *digitalis purpurea* one or more immediate pure principles to which the medical properties of this plant can be attributed?”

The essays are to be written either in French or Latin, and must be sent to M. Robiquet, the Secrétaire Général of the Society, at the Ecole de Pharmacie, Rue de l'Arbaleté, at Paris, before 1st of January, 1836, at the latest.

The conditions for the prizes are the same as at all other societies. Foreigners are admissible as candidates.—*Journal de Pharmacie.*

Extra-Uterine Fœtation.

Professor Chaussier is of opinion that the development of the uterus and the secretion of the membrana decidua, are phenomena inseparable from extra-uterine pregnancy. Various observations have shown that this opinion is too exclusive, and the point may be now considered as settled, M. Gaussail having recently met with the uterus in its ordinary condition in a female gone her full term, with an extra-uterine fœtus.

ROYAL COLLEGE OF SURGEONS.

NAMES of Gentlemen who received Diplomas during the month of February, 1835:—

J. Thomas Harland, Ashbourne; M. David O'Connell, Kilmarnock; Rich. Inaffatt, Monaghan; Wm. Deakins, Bristol; R. Sturley Munn, Colchester; John Hawkins, Peckham, Surrey; Alexander Montgomery, Belfast; F. Hutton Hill, Bath; Jas. Rodgers Williams, London; Jas. Morris, Vincent-square, Westminster; Maurice Dyte, Houndsditch; Wm. Hibbert, A.; J. Nicholls Stevens, Penryn, Cornwall; C. Burton Dashwood, Yarmouth; Brook Fishley, London; Wm. Henry, Hull; Henry Davenport, Egham; Robert Barker, Rochdale; T. Lewen Marsden, Leeds; John Chapman, Stoneleigh, Warwick; John Baird, R.N.; H. P. Lewis Drew, Gower-street, London; T. Caverhill Jerdan, E. I.; H. Foote Ling, Stogumber; A. Ed. Webber, Wellington; R. Chas. Bidden; Chas. Lingen, Hereford; A. F. Carpenter, New Ross, Wexford.

APPOINTMENTS.

Naval.—Dr. Gilbert King, surgeon to the Victory, vice Chevers, supernannated. Mr. H. D. Shea, assistant-surgeon to the Swallow packet. Mr. Joseph M. Gorman, assistant-surgeon to the Speedy cutter. Mr. H. Fossman, assistant-surgeon to the Alban steamer.

Military.—Dr. Kidd, surgeon of Portsmouth Garrison, is appointed Inspector-General of Hospitals in Nova Scotia. Mr. Keaton, surgeon to the Royal Artillery at Portsmouth, is ordered on the medical staff in Canada.

DEATHS.

In Canada, Mr. Micajah Mabey, staff surgeon to the Forces. Mr. Samuel Brien, of Ballymena, surgeon. In Quebec, Assist. Surgeon Frederick Horatio Fisher, of the East India Company's service. Mr. Thomas Watts, of Macclesfield, late house-surgeon to the Stockport Infirmary. Surg. Barker, half-pay 11th Foot. Surgeon Denny, half-pay 62nd Foot. Mr. John Williams Cartledge, of Chesterfield, surgeon, by a fall from his phaeton. Dr. John Willison, of Dundee. Mr. Francis Daniel Mudd, of Gedding, near Bury St. Edmunds, surgeon.

Mr. R. J. Kane, Professor of Natural Philosophy to the Royal Dublin Society, and of Chemistry to Apothecaries' Hall, has retired from the co-editing of the Dublin Journal of Medical and Chemical Sciences. This work will in future be conducted by our talented contributors, Dr. Graves and Dr. Stokes, assisted by Mr. Porter.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

At the Meath Hospital during the Session of 1834-5.

LECTURE II.

Case of Chronic Cough—Remarks on Bronchial Secretion—Expectoration never performed during Sleep—Effects of Catarrhal attacks frequently recurring—Account of remedies employed—Great power of Nitrate of Potash combined with Tartar Emetic, in subduing Inflammation—Observations on the Secretion of Air from the Mucous Membrane of the Intestines in certain Pulmonary Affections—Efficacy of Sulphur in Chronic Bronchitis—Sensation of Tickling which precedes Cough—Cough from Worms—Hysteric Cough—Pulmonary Irritation from a Syphilitic Taint—Pulmonary Irritation connected with a Gouty Diathesis—with a Scorbutic Habit—with Scrofula.

GENTLEMEN,—Allow me to direct your attention to-day to the case of J. Jowson in the chronic ward, labouring under an attack of exasperated chronic bronchitis, a disease which derives its chief importance from the circumstance of being exceedingly common. There is no morbid affection of the system more frequent or more general than chronic bronchitis, it is of every day occurrence in dispensary practice, it is one of those cases which you will be constantly called on, to treat, and hence the study of its nature and treatment has strong claims on your attention.

This man is, as you have seen, about the middle age in point of years, but he is old in constitution. In this country you will find most of the labouring poor exhibiting symptoms of premature old age, the combined result of poverty, intemperance, and hardship. Obligated to work in the open air in bad weather, they get catarrhal affections, which are renewed by repeated exposure, and prolonged for want of proper care. The natural effect of cold frequently renewed and generally neglected is, that a tendency is produced in the bronchial

mucous membrane to become congested and inflamed with facility, until at length the derangement becomes permanent, and the mucous membrane no longer returns to its normal and healthy condition during the intervals.

The secretion of the mucous membrane of the bronchial tubes, in a perfectly healthy person, is almost entirely destitute of matter to be expectorated. In the normal state, the secretion of the bronchial mucous membrane, though continually going on, scarcely ever exists in superfluous quantity, for a certain proportion of it is carried off by exhalation or absorption; *a perfectly healthy person, breathing a pure air, has no expectoration whatsoever.* The moisture secreted by his bronchial mucous membrane contains nothing that the expired air cannot carry away in vapour, without leaving any residuum which gradually accumulating would at length require to be expectorated. In this respect the bronchial mucus in the healthy state differs from the mucus of other membranes of the same class; but disease destroys this beautiful provision, and gives rise to a secretion of morbid mucus which cannot be gotten rid of in the usual way, and which must, therefore, be expectorated. Hence it is, that persons in whom a chronic state of congestion of the bronchial membrane has been generated by repeated colds, have a secretion of superfluous matter always going on, and are constantly expectorating. This may continue for several years without much inconvenience; the principal annoyance the patient suffers is in getting up the phlegm in the morning. At this period there is always an accumulation of fluid in the lungs after the night, during which the cough is less frequent, and expectoration less copious.

Here let me remark that although a person may cough violently during his sleep, he never expectorates. Expectoration is accomplished by the attention being directed to the chest, by an act of volition being put in force, so as to cause a constriction of the bronchial tubes and generate a current of air of sufficient strength to expel the mucus. To effect this, the mere act of coughing is not sufficient, and, consequently, *we do not expectorate during sleep*; for this purpose it is necessary for the patient to be awake.

Frequently recurring catarrhal affections, besides generating a state of chronic derangement of the mucous lining of the lungs, have a necessary tendency to produce other bad effects. Dyspnoea is an ordinary attendant on chronic bronchitis, the vesicular tissue enfeebled by disease loses its natural elasticity, and hence the act of respiration is performed weakly, and with considerable difficulty. In addition to this, the stress thrown on the air-cells and passages gives rise to emphysema and dilatation of the bronchial tubes.

When this man came into the hospital, he was labouring under an exacerbation of his chronic bronchitis from a fresh attack of cold, he also suffered from dyspnoea with a tendency to emphysema, and had been much debilitated by the frequent recurrence of his pulmonary symptoms. I do not intend to make any particular observations here on acute bronchitis supervening on chronic; it is a dangerous disease requiring prompt and careful attention. I merely refer to this case to point out the remedies which were employed and the principles which guided me in their selection.

At the time of our patient's admission, the fever which accompanied the acute attack had subsided. His pulse was tolerably quiet, neither did he present any derangement of the heart's action, and so far had escaped one of the consequences of chronic disease of the lung, namely, dilatation and hypertrophy of the right ventricle. Observe, the most important features in this case, so far as treatment is concerned, were these; there was no general inflammatory condition of the system present, he had neither hot skin, nor quick pulse, his expectoration was copious, the chest sounded well on percussion, and the only stethoscopic phenomena observed were extensive minute and moist bronchial râles. The case then stood thus, extensive bronchial inflammation with copious expectoration, unaccompanied by fever, and occurring in a debilitated constitution. All weakening measures were therefore contra-indicated. It is true that the man had dyspnoea, and complained of tightness across his chest, circumstances which might appear to demand the use of the lancet or leeches; if these means had been employed, he would certainly have experienced some relief; but in the course of a few hours the symptoms of distress would have returned, the weakness superinduced by bleeding would give rise to increased secretion into the bronchial tubes, and the patient would be worse than before. Under these circumstances we refrained from using the lancet or leeches, but, deeming it advisable to get rid of the last traces of inflammatory action, we gave the following mixture:—

R. Misturæ amygdalarum, ℥ij.,

Nitratis potassæ, ʒij.,

Tartar. emetici, gr. j.,

Tinctur. opii camphorat. ʒss.

Ft. mistura pectoralis, sumat cochleare j. amplum omni horâ, vel urgente tusse.

In explaining the rationale of this mixture,

it is hardly necessary for me to state why the almond emulsion was used. In all cough bottles it is of importance that the basis should consist of some mild mucilaginous fluid, and hence we generally employ for this purpose demulcent syrups, emulsions made with olive oil, spermaceti, or almonds, or decoctions of mucilaginous seeds and roots. With the almond emulsion we combined tartar emetic and nitrate of potash, both antiphlogistic remedies, and calculated to act with peculiar effect in relieving congestion of the bronchial mucous membrane. You are aware that nitrate of potash in large doses is a powerful antiphlogistic, and you have seen it prescribed with excellent effects in cases of acute arthritis treated in this hospital. Nitrate of potash, when given to the amount of two or three drachms in the day, combined with two or three grains of tartar emetic, is, next to bleeding, the most efficient means we possess of reducing inflammatory action, and were I to be asked what remedies I should employ in combating inflammation, supposing there were no such things as the lancet, or leeches, or calomel, I should certainly say nitrate of potash and tartar emetic. When given in small doses this combination proves also extremely serviceable in less severe cases, and it was on this account we gave it in the present instance. To this we joined the camphorated tincture of opium, convinced that its stimulant properties could not prove injurious when combined with antiphlogistics, although it would be improper to administer it alone. Experience has taught that when camphorated tincture of opium is given in cases of chronic cough with expectoration, it will (if much inflammatory action be present) check the expectoration and bring on dyspnoea. But when combined with nitrate of potash and tartar emetic, its bad effects are corrected, while its sedative influence remains unimpaired.

In addition to this, I ordered the nitro-muriatic acid liniment to be rubbed over his chest. This liniment we are much in the habit of prescribing where a rubefacient is required. It is made by diligently mixing one drachm of nitro-muriatic acid and one ounce of lard, by means of a wooden or ivory spatula. When this mixture is complete, two drachms of spirits of turpentine are added; these ingredients soon separate from, and mutually react upon, each other, so that the liniment is spoiled; we, therefore, never make it in large quantities. As his bowels were constipated, I gave him a pill composed of three grains of blue pill, quarter of a grain of colchicum, two grains of scammony, and half a grain of capsicum. Colchicum acts on the biliary secretion, particularly when combined with blue pill, and hence promotes the general action of the intestines. With these I combined a little capsicum in consequence of the patient's complaining of being annoyed by constant flatulence. It is a curious fact that every chronic derangement of the bronchial mucous mem-

brane is accompanied by flatulence. Whether this arises from the irritation of the bronchial membrane spreading by continuity of tissue, and rendering the tongue foul, the stomach weak, and the digestive function unnatural, or whether the derangement of the bronchial mucous membrane, and the imperfect performance of the function of respiration, cause the secretion of air from the lungs to be diminished, in consequence of which air is secreted from the intestinal mucous membrane by a vicarious action, I cannot exactly state, but I think the latter hypothesis not very improbable. It is well known that the mucous membrane of the stomach and bowels enjoys the power of secreting and absorbing air; it secretes carbonic acid, nitrogen, and also other gases which seem peculiar to it, such as sulphuretted hydrogen. I am not aware that there is any distinct evidence that the last named gas is ever secreted by the bronchial mucous membrane, but as there are some cases in which the breath is remarkably foetid, I think it remains for future experiments to decide whether it may not be so under certain circumstances. It is, however, by no means improbable, that when an adequate cause produces considerable derangement in the respiratory function, and alters the nature of the ærial secretion from the lung, the mucous lining of the stomach and bowels may take on a vicarious action, and secrete gases analogous to those which in the normal state are secreted by the mucous membrane of the bronchial tubes. I think I have seen some well marked examples of this translation of the function of secreting air from the pulmonary to the intestinal mucous system in cases of spasmodic asthma and hysteria. I have seen patients who, previously to an attack of asthma, had no symptoms of flatulence, and observed that accordingly as the disease proceeded and the derangement of the respiratory function increased, the bowels became distended with air. In hysteria, also, where derangement of the respiratory function is plainly denoted by the heaving of the chest, sighing, and dyspnoea, there is generally enormous and sudden inflation of the belly, loud borbyrygmi are heard, and there is a constant disengagement of air upwards and downwards.

But to return to our patient. After we had removed all traces of active inflammation, and the case had been reduced to one of ordinary chronic bronchitis, we changed his cough mixture for the following:—

R. Misturæ ammoniaci, ℥vj.
 Carbonatis sodæ, ℥ss.
 Tincturæ opii camphorat. ℥ss.
 ——— hyoscyami, ℥j.
 Vini ipecacuanhæ, ℥ij.
 Fiat mistura pectoralis, sumat cochl. j.
 amp. pro dose.

The carbonate of soda was given with the view of removing some acidity of stomach which he complained of; besides, it is a fact that alkalies produce good effects in many

cases of pulmonary irritation, as must have struck you from witnessing the success of the popular remedy for hooping-cough, recommended by Mr. Pearson. You will observe, gentlemen, how very different this cough mixture is from the former, it is much more stimulating, and at the same time more powerfully anodyne, the opium being here less diluted, and being aided by henbane; the addition of ipecacuanha was intended to prevent a too speedy action on the part of the other ingredients in diminishing the expectoration and constipating the bowels.

I wish to call your attention to the plan of treatment, not with reference to this case alone, but with respect to chronic bronchitis in general. We first gave a combination of nitrate of potash and tartar emetic with the view of removing any remaining traces of inflammatory action; we next prescribed the misturæ ammoniaci with camphorated tincture of opium and carbonate of soda, &c., and, finally, when the cough became entirely chronic, we gave the compound iron mixture with tincture of hyoscyamus in draughts, and an electuary consisting of sulphur, cream of tartar, and senna. I need not repeat what you will find in every treatise on materia medica, with respect to the use of the compound iron mixture; it is not to be given until all traces of fever and local inflammation are removed, and never until the secretion from the lungs is copious and expectoration free. In such cases the patient is generally weak, and the inordinate secretion adds to his debility. Here the compound iron mixture proves extremely serviceable, but you should commence its use with caution. Some persons are in the habit of giving it in doses of half an ounce two or three times a day; this I never do; I begin with a drachm twice or three times a day in an ounce of spearmint water, and add from half a drachm to a drachm of tincture of hyoscyamus. The dilution with mint water, and the addition of tincture of hyoscyamus, render it more valuable, by causing it to be more easily borne by the system, and less likely to be rejected by the stomach.

Let me now explain my reasons for ordering the following electuary:—

R. Electuarii sennæ, ℥ijj.
 Pulveris supertart. potassæ ℥j.
 Sulphuris loti, ℥ss.
 Syrupi zingiberis, q. s.
 Ut fiat electuarium, sumat cochleare, j.
 parvum bis vel ter quotidie.

In the first place, when giving any stimulant medicine internally it is essentially necessary to attend to the state of the bowels; in the next place, keeping the bowels freely opened has a very remarkable effect in diminishing inordinate secretion from the bronchial tubes. Where the patient's strength can bear it, I often diminish supersecretion from the lung by strong hydragogue purgatives, as you saw in the case of a patient in the chronic ward,

who had orthopnoea and such an excessive secretion into the bronchial tubes as to threaten suffocation. The patient being a strong man, and having no symptom of intestinal irritation, I prescribed a bolus, composed of a grain of elaterium, two of calomel, ten of jalap, and five of scammony, forming a powerful hydragogue purgative, which produced several copious fluid discharges. The man bore its operation well, and I repeated it in two days with the most decided benefit; indeed he experienced from it more complete relief than he would have done from bleeding, blistering, or any other remedial means. In some cases of bronchitis with excessive secretion you will be able to produce very striking effects by the use of hydragogue purgatives; this, however, will require both judgment and discretion, and it should be borne in mind, that in the majority of cases there are many circumstances which contraindicate their employment.

With respect to the use of sulphur in this case, I was led to prescribe it, in this and many other similar cases, from observing that chronic cough and long continued congestion of the bronchial mucous membrane were more effectually relieved by the use of sulphureous waters, such as the Lucan and Harrowgate Spas, than by any other remedy that could be devised. I may here also observe, that the Lucan waters produce very striking effects in diseases of the skin, and that I have seen intractable cases of psoriasis, which lasted for years, yield to the use of the Lucan waters. It would appear that sulphur when taken into the system, is either eliminated by the kidneys in the form of sulphates, or exhaled from the skin and mucous tissues in the form of sulphuretted hydrogen, and in this way we arrive at some explanation of its action in diseases of the skin and chronic irritation of the bronchial mucous membrane. In fact, paradoxical as it may appear, sulphur, although evidently stimulating, is nevertheless very efficacious in curing many diseases connected with, or depending on, inflammation or congestion. Thus exhibited internally and properly combined, what remedy gives such prompt and certain relief in that painful affection, piles? How rapidly does the specific irritation of the skin, termed scabies, yield to its use? These and similar facts, which might be brought forward in abundance, ought to countenance the use of this medicine in certain chronic inflammatory affections of the bronchial tubes. The celebrated Hoffman was in the habit of adding sulphur to his cough prescriptions in all cases of chronic bronchitis in the aged and debilitated, and I have no doubt that from five to ten grains of sulphur, taken three or four times in the day, is one of the best remedies that can be prescribed in cases of chronic cough, accompanied by constitutional debility and copious secretion into the bronchial tubes. Within the last four years my attention has been particularly directed to the use of sulphur

in this and other affections, and I can state from experience that it is a most valuable remedy. As it has a tendency to produce elevation of the pulse, increased heat of skin, and sweating, it will be necessary to temper its stimulant properties by combining it with cream of tartar, which is a cooling aperient, and has the additional advantages of determining gently to the kidneys*. The addition of the electuary of senna gives additional value to the combination, and quickens its action on the intestines.

Such, gentlemen, are the principles that guided me in prescribing for this man. The long continuance of the complaint, the serious and extensive derangement of the pulmonary mucous membrane, the age, debility, and impoverished circumstances of the patient forbid me to hope for a perfect cure; but he has been much relieved, and the same remedies applied to less desperate cases would have produced very striking effects. Still, if fortune were this moment to prove favourable to the poor fellow, if, when he leaves the hospital, instead of returning to hardship and exposure, he had the means of living in comfort, taking proper care of himself, travelling for health and amusement, and using a course of chalybeate spa waters, I have little doubt that with these aids the reparative powers of nature would succeed in obliterating every trace of pulmonary derangement.

Permit me, gentlemen, to make a few observations here on what is popularly termed, cough. What is cough?—A sudden and violent expulsion of air from the lungs, produced by forcible contraction of the diaphragm, aided by the abdominal and other expiratory muscles. What is the cause of cough?—Pulmonary irritation. What is the nature of this pulmonary irritation?

Here, gentlemen, is a question which every practitioner should put to himself when called on to treat a case of cough, and what affection is there which so frequently demands our assistance and tasks our ingenuity? How abundant, how varied, are the examples of cough we meet with in our daily practice! How obscure do we not find its nature on many occasions, and how difficult and perplexing its treatment! Where the source of irritation is manifest, where the nature of the disease is simple and easily detected, where, after a proper examination, we can point to some part of the respiratory system, and say here is the seat of the disease; in such cases, indeed, our course is sufficiently clear, we may proceed with confidence and practice with success. But how often are we, after weeks and even months of close and painful attention, baffled in our best directed efforts, and forced to admit the humbling conviction that all our remedies are inefficient and useless, and that

* Baglivi has well said, "In morbis pectoris ad vias urinae duceudum est."

our character as well as that of the profession is likely to suffer in public estimation? How often, too, do we discover with surprise, that the cough which we have been treating for weeks as a pure pulmonary affection, depends not on any primary derangement of the respiratory system itself, but upon the irritation of some distant organ, or upon peculiar conditions of the whole economy?

Before I proceed to inquire into the nature of the various sources of pulmonary irritation producing cough, I wish to remark that the exciting cause, or, in other words, that which immediately precedes and seems to give rise to a tendency to cough, is a sensation of tickling in the mucous membrane of the trachea, close to its bifurcation, and opposite the hollow at the fore part of the neck. It is also a curious fact that this sensation of tickling or itching is peculiar to this situation, being never felt in any other part of the pulmonary mucous system. Whether the disease be seated above, as in case of laryngeal affections, or whether it be below, as in case of disease of the lining membrane or parenchyma of the lung, it is here alone that the tickling sensation is felt. Another circumstance equally remarkable and equally difficult of explanation, is the effect of position in cough. Persons labouring under slight bronchitis, or rather slight inflammation of the trachea, who scarcely cough half-a-dozen times during the course of the day, will, the moment they lie down at night, be seized with a violent and harassing cough, which may last for several minutes, and sometimes for hours, with little intermission. We can easily understand why empyema or pneumonia of one side of the chest may produce cough in certain positions and not in others, for here we have an obvious physical cause; the accumulated fluid in the pleural cavity in the one case, and the diseased lung, whose specific gravity has been much increased by solidification, in the other, exercise an inconvenient degree of pressure on the sound lung, and hence give rise to irritation and cough, particularly in those positions which favour the operation of these physical causes of irritation. Here, however, the cause of irritation is very obscure. It may (but this I merely offer as an hypothesis) depend on the fluid secreted by the mucous membrane trickling over that part of the trachea where the tickling sensation is felt, the flow of mucus to this part being favoured by the recumbent position. That it does not depend on any supposed temporary congestion and irritation of the lung, from the impression made on the skin by cold bed-clothes, I am quite convinced, for I have repeatedly observed it in persons warmly dressed, from merely lying down on a sofa close to the fire. You will, therefore, bear in mind, gentlemen, that although usually, when coughing is induced by any sudden change of position, we may infer that it is connected with some

serious lesion of the lungs, or pleura, yet we must not attach too much importance to this symptom in arriving at this conclusion, for cases are occasionally met with, in which mere tracheal, or bronchial, inflammation is attended with the same symptom to a very remarkable degree.

I may observe, *en passant*, that the sensation of tickling, or itching, appears to be almost exclusively confined to the skin. Here it appears to be dependent on slight causes, apparently incapable of producing that modification of nervous sensation, termed pain. In other cases it seems to be connected with the rise and decline of the phenomena which indicate inflammatory action, arising in the first case (where it is generally less observable) from that nervous modification which precedes inflammation, and in the second being connected with some change in the nerves of the part which precedes its return to a healthy condition. It does not appear to affect the mucous tissues, except in a very slight degree, and under peculiar circumstances. It is not observed in the pulmonary mucous tissue, except at that part of the trachea which I have already mentioned, and it does not occur in any part of the intestinal mucous membrane. The only parts connected with the intestinal tube, in which it is felt, are the nose and on the anus, and here it is within the reach of scratching, the ordinary mode of relief. This is a fortunate circumstance, gentlemen, for if any part of your bowels were to itch as your skin sometimes does the annoyance would be quite intolerable. If the presence of lumbrici in the small intestines, instead of producing a troublesome itchiness of the nose, as it often does,—if it produced, I say, a degree of itching equally intense in the mucous membrane of the bowels and stomach, what patient could endure greater torments than a person so afflicted? If ascariides gave rise to as intense a degree of itching within the colon, as they occasion at the verge of the anus, how dreadful would be the suffering thus induced!

Passing over the obvious and well known sources of pulmonary irritation, producing cough, such as bronchitis, pneumonia, &c., the first cause to which I shall direct your attention is one of not unfrequent occurrence, and where a mistake in diagnosis may lead to a practice useless to the patient and discreditable to the practitioner. The best mode of illustrating this is by giving a brief detail of a case which I attended with Dr. Shekleton. A young lady, residing in the neighbourhood of Dorset-street, was attacked with symptoms of violent and alarming bronchitis. The fits of coughing went on for hours with extraordinary intensity; it was dry, extremely loud, hollow, and repeated every five or six seconds, night and day, when she was asleep as well as when she was awake. Its violence was such that it threatened, to use a vulgar but expressive phrase, to tear her chest in pieces, and all her friends wondered how her frame

could withstand so constant and so terrible an agitation, and yet she fell not away proportionally in flesh, had no fever, and her chest exhibited nothing beyond the râles usually attendant on dry bronchitis. She was bled, leeched, blistered, and got the tartar-emetical mixture, but without experiencing the least relief. We next tried antispasmodics, varying and combining them in every way our ingenuity could suggest, still no change. We next had recourse to every species of narcotics, exhibiting in turn the various preparations of conium, hyoscyamus, opium, and prussic acid, but without the slightest benefit. Foiled in all our attempts we gave up the case in despair and discontinued our visits. Meeting Dr. Shekleton some time afterwards I enquired anxiously after our patient, and was surprised to hear that she was quite recovered and in the enjoyment of excellent health. *She had been cured all at once by an old woman.* This veteran practitioner, a servant in the family, suggested the exhibition of a large dose of spiritus of turpentine, with castor oil, for the purpose of relieving a sudden attack of colic, two or three hours afterwards the young lady passed a large mass of tape worm, and from that moment every symptom of pulmonary irritation disappeared.

The next kind of cough, in which the cause of pulmonary irritation is often misunderstood, is that which occurs in hysteric females. This kind of cough is one of the most alarming diseases in appearance you can possibly witness; in some it is loud, ringing, incessant, and so intensely violent, that one wonders how the air-cells, or blood-vessels, escape being ruptured. In others it is quite as incessant, occurring every two or three seconds, night and day, but is not very loud, and, indeed, in some it scarcely amounts to more than a constant teasing hem; in general the pulse is quick, but it is the quick pulse of hysteria, not of inflammation or fever. The patient suffers no aggravation of the cough from inspiring deeply, and her countenance exhibits no proof of malæration of the blood, on the contrary it is blanched and pallid. She complains of variable, or deficient, appetite, headache, cold feet, and irregular or absent catamenia; although the cough continues for weeks, or even months, she does not emaciate like a person in incipient phthisis, although so much disturbed by the cough, and subsisting on so small a quantity of food.

Here the history of the case, a knowledge of the patient's habit, and the use of the stethoscope are of great value. You will find that the patient is subject to hysteria, that she is generally pale and of a nervous habit, that the attack came on suddenly, and was superinduced by mental emotion, or some cause acting on the nervous system, or else arose gradually as one of the sequelæ of catamenial disturbance, that the heat of skin and state of pulse are by no means proportioned to the violence of the symptoms, and the stethoscope will tell you

that the signs of organic derangement of the lung are absent. You will thus be enabled to arrive at an accurate notion of the nature of the disease, and you will save the patient from the useless and often dangerous employment of antiphlogistic means. Bleeding and leeching are, generally speaking, injurious; such cases are best treated by stimulants, antispasmodics, and stimulant purgatives, together with change of air, travelling, and the use of chalybeate spa waters.

The third species of obscure cough, to which I shall direct your attention, is one of deep importance for many reasons. It is that species of cough which depends upon pulmonary irritation connected with a venereal taint in the system. That syphilis may attack the pulmonary as well as the cutaneous, osseous, mucous, and other tissues, is not a discovery of modern times; it is a form of the disease long known, and you will find it mentioned by many of the older writers. Since syphilis has been classed by Willan and others among diseases of the skin, this notion seems to have been either abandoned or forgotten, but, as it strikes me, with very little justice. I entertain a firm conviction, that syphilis may affect the pulmonary as well as it does the cutaneous, or mucous, or osseous tissues, and that a patient, labouring under a venereal taint, may have irritation from this cause set up in the lung as well as in any of those organs in which it is usually manifested. The first person who mentioned this circumstance to me was the late Mr. Hewson, and since that time I have had repeated opportunities of confirming the truth of his opinion. Richter, Alibert, and Paget have well observed, that Willan and Bateman's classification of diseases of the skin is liable to the paramount objection, that it has no reference to the constitutional origin of cutaneous affections. I have the very same fault to find with modern treatises on diseases of the lungs. Pathologists have indeed inquired most accurately into the numerous morbid changes to which the pulmonary tissue is subject, but they have omitted a no less important part of their task, which is to investigate the states of constitution which originated these changes. The agency, indeed, of scrofula has been inquired into with care, but how little attention has been paid to rheumatism, gout, syphilis, and scurvy, the fruitful sources of numerous diseases of the chest.

By far the most interesting point, connected with this affection, is its diagnosis; on this every thing depends. The great importance attached to the diagnosis arises from the circumstance of this disease presenting symptoms analogous to, and consequently being frequently confounded with, phthisis. A patient comes to consult you for cough; you find him pale, emaciated, and feeble; he sleeps badly, and is feverish at night, and has a tendency to sweat. Here there may be a double source of error. If the disease be mistaken for tubercle, and mercury not given, bad consequences will

result; on the other hand, if tubercles be present, the effect of administering mercury will be to precipitate the disease to a fatal issue.

What is the nature of this disease, and how are you to recognise it? Mainly, I answer, by the history of the disease. If the patient's sufferings have commenced at the period of time, after primary sores on the genitals, when secondary symptoms usually make their appearance; if some of his complaints are clearly traceable to this source; if, along with debility, night-sweats, emaciation, nervous irritability, and broken rest at night, we find cough; and if this group of symptoms have associated themselves with others, evidently syphilitic, such as periostitis, sore throat, and eruption on the skin, then we may, with confidence, refer all to the same origin, and may look upon the patient as labouring under a syphilitic cachexy, affecting the lungs as well as other parts. In forming this diagnosis much caution and care are necessary, and we must not draw our conclusion until we have repeatedly examined the chest by means of auscultation and percussion; if these fail to detect any tangible signs of tubercles, we may then proceed to act upon our decision with greater confidence, and may advise a sufficient but cautious use of mercury. Under such circumstances it is most pleasing to observe the speedy improvement in the patient's looks and symptoms; the fever, night-sweats, and watchfulness diminish, he begins to get flesh and strength, and, with the symptoms of lues, the cough and pectoral affection disappear. I am not prepared to say which of the pulmonary tissues is most usually attacked by the venereal poison, but I believe that it chiefly tends to the bronchial mucous membrane, although, like other animal poisons, *e.g.*, those of measles and scarlatina, it may also occasionally produce pneumonia.

The fourth species of obscure pulmonary irritation, producing cough, is that which is connected with a gouty diathesis. Gout may attack almost every tissue in the body. We may have it in the joints, as you are all well aware of, we may have it in the muscles and muscular aponeuroses, forming what has been termed the rheumatic gout; it occurs frequently in the fibrous tissues, and I have several times observed it in the cellular substance of various parts of the body, forming either diffuse œdema or tumours, which are exceedingly tender to the touch, and which are removed by treatment calculated to relieve the constitutional affection. It may attack the heart, giving rise to true pericarditis, or else to a functional disease with palpitations, a sensation of fluttering and sinking about that organ, and very remarkable intermission of the pulse; or it may affect the stomach, occasioning dangerous spasm, or various dyspeptic symptoms; or it may seize on the intestines, producing irritation, colic, and gouty diarrhoea. I remember a patient, of a confirmed

gouty habit, expressing a great deal of surprise at getting an attack of gout in the testicle, for he could not conceive how a disease, which generally affects the joints, could occur in an organ so different in its nature. I replied that the matter could easily be explained; because fibrous tissue, which gout most frequently attacks, enters into the composition of the testicle as well as that of the joints. Indeed the testicle, with reference to the texture of its envelopes and the extent of motion it enjoys, may be said to be provided with a sac-like joint. In like manner, gout very frequently attacks the mucous membrane of the trachea, or bronchial tubes, causing a dry, annoying, and often a very obstinate cough. Where this cough comes on along with the fit of inflammation of the joints, it is true nature is frequently overlooked, and it is believed to have originated in cold, and to be mere common bronchitis. No matter, gentlemen, what be the cause of inflammation in a gouty habit, no matter what the organ attacked by the inflammation be, it almost invariably assumes the character of true gouty inflammation. If a gouty person sprains a toe, or an ankle, matters, after progressing for a time in the ordinary way, are sure in the end to exhibit a change of character, and the inflamed parts are observed either to grow unexpectedly worse, or to become stationary, at a time when a speedy termination of the local affection seemed approaching. This is owing to its being now modified by the constitutional tendency to gout, which localises itself in the affected part. Precisely the same relations may be often observed between common bronchitis, produced by cold in a gouty habit, and the gouty bronchitis it indirectly produces. Gouty bronchitis often becomes chronic, continuing until it is relieved by a regular fit of the gout in the extremities.

The fifth species of pulmonary irritation, in which the source of the disease is more or less obscure, is that which is connected with the scorbutic diathesis. It is important to be aware of this, particularly for those who have charge of the health of the poorer classes, which is almost of more value than that of the rich, for on it their labour and their means of support depend. Among the poor, particularly in cities where the majority live on salt provisions, the scorbutic diathesis is very prevalent. It manifests itself either in the form of purpura, or in tendencies to hæmorrhage from the nose, stomach, bowels, and bladder. It sometimes attacks the lungs, producing irritation of the bronchial mucous membrane, with cough, and spitting of blood, and occasionally gives rise to pulmonary apoplexy. It is evident that pulmonic cases of this nature, originating in a scorbutic diathesis, produced by confined air, damp lodging, and a salt diet, will require a treatment peculiar to themselves, both during the attack and during convalescence.

The last source of pulmonary irritation, to

which I shall direct your attention, is that which proceeds from scrofula. You all know that scrofula has a tendency to attack every tissue in the body, but you may not perhaps be aware, that it may affect those tissues in very different ways, and that scrofulous irritation may manifest itself in various forms, from the most trifling and transitory to the most extensive and permanent. I recollect a case I attended with Dr. Jacob, in which this fact struck me very forcibly. A fine boy of high complexion, precocious intellect, and other marks of the scrofulous diathesis, got an attack of scrofulous ophthalmia of an intense character, and it required all the skill and ingenuity of Dr. Jacob to save him from blindness. During the period of our attendance, his brother (who was also of a strumous habit) began to complain of parts of his arm being sometimes a little sore. This circumstance attracted my attention, and on examination I found that several circular diffused swellings, of various sizes, often equalling half a crown in diameter, had successively appeared on different parts of his extremities and body. They evidently depended on inflammation of the sub-cutaneous cellular tissue, and exhibited a remarkable example of a most transitory local affection, produced by a constitutional cause, for these swellings arose, arrived at their acmé, and subsided in the space of ten or twelve hours; they constituted, in truth, the first efforts of the scrofulous diathesis, to localise itself, and, after a few weeks' continuance, they were replaced by distinct and fixed scrofulous inflammation of the metatarsal bones.

Here was a very curious and instructive fact. A boy, evidently of a scrofulous diathesis, has circumscribed tumours, which arise, come to maturity of irritation, and subside in the course of a few hours. In some weeks afterwards, scrofulous irritation, in a decided and permanent form, fixes itself in the foot, producing inflammation and ulceration. From this it may be inferred, that scrofula (for in this case I am firmly convinced these tumours were connected with strumous diathesis) may attack parts not only in its more permanent and destructive forms, but also in a manner so trifling and so transitory, as to subside in a few hours and leave no trace of its existence. The inferences deducible from this fact are numerous and important, for if scrofula may thus produce an acute and transitory inflammation of the subcutaneous cellular tissue, surely it may occasionally give rise to somewhat similar affections of internal organs, as the bowels, the lungs, &c., and thus may occasion an acute bronchitis, a pneumonia, or an inflammation of the mucous membrane of the intestines, totally independent of the operation of cold, or the usual causes of such affections. It has been too much the custom to refer merely chronic and fixed local inflammations to the agency of constitutional causes. The example before us proves that even the most transitory may have this origin.

Scrofulous irritation may affect either the lining membrane or the parenchyma of the lung, giving rise in the one case to scrofulous bronchitis, in the other to scrofulous pneumonia, two affections which may exist separately or combined, and either of which may prove fatal, with or without the development of tubercles in the lungs. Tubercles have, as I have elsewhere proved, too exclusively engrossed the attention of those who have investigated the pathology of phthisis; they are a very frequent product of the scrofulous diathesis, but the scrofulous bronchitis and scrofulous pneumonia are still more frequent and more important, and do not, as is falsely supposed, depend upon the presence of tubercles in the lungs. The pneumonia, the bronchitis, and the tubercles, where they occur together, are all produced by one common cause,—scrofula. Of this more hereafter.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXII.

*Prognosis and Treatment during and after
Labour.*

GENTLEMEN,—Having described to you the various species of eutocia, I now proceed to the prognosis and treatment, both during and after labour. “The more active and free from pain the patient is in her loins and feet, and the less she suffers from fulness and pain in the head, &c., at the commencement of labour, the better and easier will it be *.” To insure this favourable state of the system, it will be necessary that the bowels should be kept moderately open by castor oil, and if there be the slightest reason to suspect that the bowels are at all loaded at the beginning of labour, an injection will be requisite; by emptying the rectum the head experiences less difficulty in passing through the cavity of the pelvis, the uterus is excited to stronger pains, and the labour is thereby rendered cleanly, which otherwise would be so disgusting to the patient, as well as the accoucheur, because the sphincter ani being deprived of all power from the great degree of distension, which the parts are made to undergo, any fecal matter, which may happen to be in the rectum, is involuntarily expelled when the head comes on the perinæum. “At the beginning of labour the abdomen (in a front view) has by no means a globular but rather an elliptical oval figure.

* Wigand Geburt des Menschen, vol. ii.

* * * * About the middle of labour it becomes somewhat smaller, lower, and more oval; towards the end of labour, when the uterus, from the advance of the child and escape of the liquor amnii, becomes diminished in size, the inferior half alone appears much distended, while the superior part, or fundus, is flatter. * * * The more the figure of the abdomen, at the beginning of labour, approaches to the state in which it is at the third or fourth stage, the quicker the labour will be, * * * for in this case the uterus assumes a pyriform figure, and the more it does this the more powerfully it acts, and the progress of the labour will be proportionally more rapid.*' The smaller the uterus is at the beginning of labour the easier will be its course, a large uterus shows distension, with lymph, blood, liquor amnii, twins, or a very large child, and therefore generally indicates a slow labour.

The *position*, in which the patient should remain during labour, and in which it is most favourable for her to be delivered, has been a subject of considerable discussion, more especially upon the Continent during the last century, where much has been written about it. In former times it was the custom for the husband to take her upon his knees, and for her to be delivered in this posture. H. Van Deventer first brought the labour chair into general use in Holland and the Low Countries, but he must not be considered as the inventor of it, because the celebrated surgeon, Ambrose Paré, so early as 1573, speaks of a labour chair with an inclined back, which he prefers to the common bed. Deventer's chair was in such request throughout Holland, that it was the common present to a young woman on her marriage day: almost every professor invented a new chair, which went by his name, much in the same way as they do now with the forceps. The principle of these labour chairs is the same throughout, all of them are more or less furnished with straps, cushions, &c., by which the patient can fix her extremities, and thus allow the abdominal muscles to act with the greatest power, and certainly, if our object be only to accelerate labour, they are very good, but our object is not that the child should be born as quickly, but as safely, as possible; a rapid labour is never desirable, either for the mother or the child; from being able to assist her pains so powerfully, the head passes through the external passages before they have had time to dilate sufficiently; hence, as Tolver remarked in 1770, "at Brussels, where Deventer's chair is indiscriminately used, lacerations of the fourchette and perinæum are very frequent." In France these chairs have ceased to be used for the last eighty or ninety years, and the women are delivered lying on their back. In England, as far as I know, they have never been used, and the women, for the last century at least, have

been delivered on a common bed, on their left side. This was at one time called the Burton position, from Dr. John Burton, of York, who published a work on midwifery in 1751, but the advantages of lying upon the left side were known long before Burton's time, for Fielding Ould, whose work appeared in 1742, says the side is certainly the most advantageous posture for natural labour. In Germany the practice varies at the different schools of midwifery; in some the patients are delivered on their backs as in France, in others upon their left side as in this country, while at Berlin and Dresden a peculiar cushion for the purpose has been used by the late Professor Von Siebold and Professor Carus.

As soon as the os uteri begins to dilate we should endeavour to ascertain the position of the child; instead of *taking a pain*, as it is called, or, in other words, making the examination during the pains, as is commonly directed, examine during the intervals, otherwise the membranes may be prematurely ruptured, the liquor amnii will escape, and thus the labour be considerably retarded. You cannot be too cautious in this respect, especially in primiparæ, where the membranes are so liable to give way at an early stage; besides, during a pain the membranes become so tense, that it is impossible to ascertain the position of the child. The patient may take whatever posture she likes, until the os uteri is fully dilated, and the membranes ready to burst; it is now the proper time to put her upon her left side, because in many cases, especially in those who have already had children, the child is apt to follow the rupture of the membranes very quickly; all the preparations for assisting the patient's exertions, as towels to hold by, or cushions and pillows to pull or push against, are in my opinion not desirable. I am no friend, gentlemen, to rapid labours, for those which are slow and gradual are, properly speaking, the only healthy ones.

If the accoucheur has not been certain of the nature of the presentation before the rupture of the membranes, he should examine immediately upon its taking place; even if he does know how the child presents, he should examine at this moment, to ascertain what progress it has made, and whether, also, the umbilical cord be not prolapsed. All violent straining, all attempts to dilate the os uteri artificially, as by rubbing in fat, butter, &c., are highly injurious, nor do they ever attain their object, for, by irritating and inflaming the os uteri, they only serve to prolong the labour. Much has been written on the means of hastening labour; thus Stein wrote a treatise entitled, "*De Novâ Enchyrafi ad Partum accelerandum.*" In primiparæ, where the patient is young, robust, and plethoric, where the pains are irregular and inefficient, where there is any disposition to pain of head, or where the abdomen is unusually painful, both during, and between the pains, venesection

* Wigand Geburt des Menschen, vol. ii.

will be of the greatest benefit; the pains become regular, and act more powerfully and efficaciously upon the os uteri, which becomes also more dilatable. In labour not greatly protracted, as says Mr. Burns, it is better to trust to clysters, to gentle motion, and change of posture, or to sleep, if it offer naturally, and the patient be recruited by it; if, however, she be fatigued and debilitated, the pulse weak, &c., a smart clyster, followed by thirty drops of laudanum, does not suspend the pains, but rather excites them; but in tedious labours, where there is heat of skin, full pulse, thirst, and restlessness, where the passages are hot, dry, rigid, and tender, the pains severe, but inefficient and irregular, venesection will be very beneficial.

The pains do not compel the patient involuntarily to strain and bear down, until the head has passed the os uteri and entered the vagina, and the accoucheur can frequently tell, the moment he enters the room, how far the labour is advanced, by the tone in which the patient expresses her sufferings. The abdominal muscles are not called into action by the pressure of the head upon the rectum producing a vehement call to evacuate the bowels, but from that peculiar sympathy which exists between the os uteri, vagina, and abdominal muscles, for in cases where the os uteri is pushed down very low in the pelvis, and is but little dilated, there is no incitement to strain. You are aware that in primiparæ the head is felt very low in the pelvis for some days before labour, and yet, with all this, we find that no involuntary efforts to bear down are produced, although, from its position in the pelvic cavity, the head must have exerted considerable pressure upon the rectum. As I before told you, gentlemen, when speaking of labour, the violent straining pains which come on towards the latter part of labour, arise from the immense distension which the vagina suffers at this moment; it seems to have the same sympathetic connexion with the abdominal muscles, as the sphincter ani and rectum have. Thus, at the moment when a large mass of fecal matter is passing through the rectum, the abdominal muscles are involuntarily excited to bear down. The tenesmus of dysentery is merely a modification of the same; the rectum is highly irritated, and the abdominal muscles instantly sympathise.

Upon no subject is the accoucheur so liable to be importuned, than as regards the probable duration of the labour, and upon no subject is it more difficult to form an opinion upon any grounds of certainty. Wigand, who paid minute attention to the whole process of labour, and every thing connected with it, asserts that he could generally form a pretty accurate prognosis as to the duration of labour, by ascertaining the configuration and state of the vagina. For instance, if he found it to be narrow throughout, to be cool, dry, rather rough than smooth, and unyielding, it was a sign that the course of labour, both at its com-

mencement and termination, would be slow and difficult. If, however, the entrance of the vagina be small and but little developed, but its cavity sufficiently roomy, soft, warm, moist, &c., we may expect the labour to proceed with tolerable briskness at the commencement, but towards its close to become slow and lingering. If, on the other hand, an opposite configuration be present, where the entrance of the vagina is well developed, but the upper half contracted, the labour, although lingering at its commencement, will become rapid during the latter part. Lastly, where the vagina, throughout its whole extent, is equally spacious, warm, moist, &c., &c., we have every reason to anticipate a speedy and easy labour. He assures us that, by attention to these points, he has frequently been enabled to form a very certain prognosis as to the duration of labour, and, in some few cases, where the form of the vagina has been well marked, I have found his observations borne out by experience.

Very tedious or very rapid labours seem to be almost hereditary in some families, and we not unfrequently find where two or three sisters have had unusually slow and lingering labours, that their mother was remarkable for the severity of her labours also. It has been also observed, in cases where the patient has borne all her children several weeks before the time, that this disposition to premature labour has been also remarked in other members of her family. La Motte gives two or three instances where the pregnancy terminated seven months after marriage, and where the patient had thereby excited the suspicions of her husband, every succeeding labour came on at the same time, and, in one case, the daughter of the lady showed a similar disposition to early labour.

The management of the perinæum during labour is a subject of considerable importance, the more so because it is one to which your attention will be more or less required in every labour. Towards the end of labour the perinæum becomes excessively distended by the pressure of the head against it, so much so, that a person who had only seen it in its natural state would scarcely believe it were capable of undergoing such immense distension, but that it must be inevitably ruptured before the head could pass. Its astonishing powers of dilatation can scarcely be ascribed to mere elasticity; might not we rather presume that some change in its structure, similar to that in the vagina, had taken place during pregnancy?

There are two moments at which laceration of the perinæum is peculiarly liable to take place, viz.—when the head and when the shoulders are passing through the os externum. Of the two, I consider the latter by far the most dangerous, for we frequently find, where a very trifling laceration has been produced during the passage of the head, that this has been converted into a wide rent when the shoulders have passed. To prevent laceration,

we must retard the progress of the head through the external parts as much as possible, for the longer the perinæum has time to dilate, the liability to rupture will be proportionately diminished; for the same reason, also, we must desire the patient not to strain. In order to insure this more effectually, we must put her into a posture in which she cannot exert her strength with full effect; thus, for instance, upon the back or side, where the loins are not fixed. The best position is upon the left side, for the pains are more tolerable in this than in any other. Instead of separating the knees with cushions, as is usually done, it is better to put them close together, for this contributes still more to save the perinæum.

Supporting the perinæum has been recommended so long ago as by Puzos and La Motte: it consists in applying the palm of the hand firmly against the perinæum, when this is distended into a round tumour by each pain, with a soft napkin interposed to prevent the hand from slipping, and also for the sake of cleanliness, and this should be changed as often as it becomes wet. The object in supporting the perinæum is to make the hand act instead of it, that is, to make the hand sustain the pressure of the head, until the perinæum has had time to dilate sufficiently. The best mode of supporting the perinæum is with the left hand, because then the right is at liberty to execute any manipulations which may be required. The examining finger of the right hand is also of great service in determining the exact direction which the left should take, and gives instant warning when its support is really necessary.

The late Dr. Hamilton, of Edinburgh, considered it as unnecessary, and this opinion has been lately supported by Professor Mende, of Göttingen, and certainly there are cases where supporting the perinæum is not necessary, but, on the other hand, there are cases where, do what you will, you cannot prevent a laceration. I remember a case where, from the smallness of the os externum, a laceration was deemed inevitable; the gentleman in charge of the patient determined that this should not take place; upon the birth of the child no rupture of the perinæum was observed, *but the left labium was torn across*. The *frænum perinæi* is always torn in first cases, but a considerable laceration into the substance of the perinæum does not occur frequently: when, however, it does happen, little more than mere attention to cleanliness is required, for the parts contract so astonishingly after labour, that what was a wide rent of an inch and half long, in a couple of days will be scarcely more than two or three lines in length; hence, generally speaking, rupture of the perinæum heals very rapidly. The absurdity of the old plan of inducing constipation for a few days cannot be sufficiently exposed, for, when the indurated *fecæes* do pass, they tear open the wound again; rest, great cleanliness, and gently relaxed bowels constitute

the chief treatment. For further information, however, upon this subject, I cannot do better than refer you to Dr. Denman's Essay on Natural Labours, where he speaks about the management of the perinæum.

When the laceration extends into the rectum, the case becomes excessively troublesome and difficult to cure, and *unless* we effect a cure the unfortunate patient is rendered miserable for life. In these cases, the slightest movement of the thighs alters the position of the lips of the wound, and thus tears it open afresh; nor can this be entirely prevented, even by the aid of adhesive plasters or sutures; the edges gradually become callous, and a gaping cleft is the result. Another practitioner now, perhaps, takes charge of the patient, the edges of the laceration are pared afresh, fresh sutures and adhesive straps are applied—but in vain. In obstinate cases of this sort, which had been deemed incurable, my friend, Dr. Dieffenbach, of Berlin, has succeeded in producing complete reunion by the following operation:—having pared away the callous edges of the wound, he brings them together in close apposition by means of the fine lace pins, which he uses in the hare-lip operation and other incised wounds of the face, and, to prevent any movement of the thighs from acting upon the wound, he makes an incision into the cellular tissue on side of it, running parallel with and at a little distance from it; by this means the wound is, as it were, insulated from the neighbouring parts, and the process of cicatrisation proceeds without interruption; the others, being fresh incised wounds, readily granulate from the bottom, and, by the time they are healed, the original laceration is completely united. Dr. Dieffenbach assured me that he found this method succeed perfectly in several cases which had been pronounced to be incurable.

As soon as the head is born, we must examine whether the cord be twisted round the child's neck or not; we should at the same time support the shoulders, because, as I before stated, if but a very small laceration in the perinæum has taken place, it will be sure to be increased. In this position the face swells, but still we must not apply any extractive force to the head in order to hasten the delivery of the shoulders, as the uterus does not always contract immediately after a sudden evacuation of the contents, and may therefore give rise to hæmorrhage.

Supposing the cord be round the child's neck, what are we to do, gentlemen? It is twisted either tightly or loosely; if loosely, you well know it by the face not becoming dark or much swelled,—leave it to nature. The works on midwifery direct that it should be pushed over the head. Oh, yes; they can do it easily enough when it is loose, and then it is scarcely necessary, for we can push it over the shoulders, and that is a much shorter plan; but if the cord be tightly twisted round the neck, the face swelled and black, it is im-

possible to turn it over the head. It very rarely happens that we cannot pass it first over one and then the other shoulder, but when we cannot, it has been recommended to make two ligatures, divide the cord between them, and then extract the child. Now by the time we have done all this, the child runs a pretty good chance of dying from strangulation, or from pressure upon the cerebral vessels; in these cases it is best merely to cut the cord with a blunt rough edged pair of scissors, and, where it is possible, to catch hold of the bleeding extremities of the cord, and hold them between the finger and thumb until the rest of the child be born, and if the child does lose a spoonful or two of blood it is not of great importance. As long as the cord continues to pulsate we should not be in a hurry to tie it and separate the child from the mother. What need is there to hurry?—place the child close by its mother, so as to keep it warm, and wait patiently until the cord has ceased to beat. I have known cases where the cord has been tied prematurely, that the child has given two or three convulsive struggles and ceased to breathe, although it had cried but a moment before. When the cord ceases to beat it should be tied with a narrow piece of tape about two inches from the abdomen of the child; this should be done firmly, and with your hands resting against each other. I never put but one ligature upon the cord, for it is much better to allow the placental extremity to bleed, as we thus drain the placenta of ʒij . to ʒijj . of blood, which facilitates its expulsion and favours the contraction of the uterus; where there are twins, it may be as well, for appearance sake, to place a second ligature upon the cord, but there is no real use in it, for I know of no twin case where the foetal circulations of the placenta have been connected with each other. It has been a question whether it was really necessary to tie the cord at all. When the breathing has been perfectly established, and the pulsation of the cord entirely ceased, we may cut it with a pair of blunt rough edged scissors, and no blood will follow; I say *blunt*, because we thus produce a degree of laceration and contusion in the coats of the umbilical arteries, which cause a greater degree of contraction; thus we see in a state of nature that animals instinctively bite and pull at the cord until it is so lacerated that it separates, and yet no bleeding follows. I have known cases where, from a sudden accession of violent pain, the child was born before the mother has been able to reach her bed; it has been thrown upon the floor with considerable force, and the cord ruptured, but no hæmorrhage from the cord has followed. Nevertheless in civilised life it is by no means safe to leave the cord without a ligature; circumstances will sometimes occur, where, from improper swaddling or other causes, an impediment to the respiration has been produced, and the former circulation has to a degree

returned, and thus the child has bled to death; in ninety-nine cases out of a hundred it might possibly succeed, but it is not safe, and we are only running an improper risk.

As soon as the child is separated and taken away, we must lay our hand upon the abdomen, firstly, to ascertain if the uterus be hard and contracted, and secondly, whether it remains so. This, gentlemen, is of the greatest importance, for I can assure you that more women die from hæmorrhage after labour and from its effects, than from all the difficult labours: this was long ago noticed by that accurate observer, La Motte, who says, "it is certain that more women perish after natural deliveries by some error or other, than after the most painful and laborious ones." Recollect that in no case are we secure against hæmorrhage; the blood may be prevented escaping by coagula stopping up the os uteri and vulva, or from the placenta lying over the os uteri, or in the vagina. This species of clandestine hæmorrhage, viz. where the blood collects in the cavity of the uterus, is particularly to be dreaded; this is what is called *internal uterine hæmorrhage*. Our first act then must be to place the hand upon the abdomen; if it feel hard, and about the size of a child's head, there is no cause of apprehension. Even when the uterus has contracted sufficiently and expelled the placenta, still your patient is not free from danger; the uterus may again relax, become soft, and swell, and hæmorrhage come on; for this reason the accoucheur should, if possible, remain within call for the first few hours, in order that he may be with her at the shortest notice; it is here where the value of a sensible judicious nurse is seen.

According to the usual course of things, the pains, which had ceased upon the birth of the child, return in eight or ten minutes, a small quantity of blood generally makes its appearance, which shows that the placenta is becoming detached, and if, on passing your finger along the cord, you feel the placenta in the os uteri, you may be tolerably certain that it is now entirely separated from the uterus; if, however, it be not within reach of the finger, we may conclude that it is still wholly or partially adherent.

If the placenta be still adhering, we are recommended to apply gentle friction to the abdomen with our hand, in order to excite the uterus to contract; but Professor Naegele rather deprecates this plan, as tending to induce irregular contractions in the lower part of the uterus. I cannot say that I have seen this result. What I have found answer the purpose best, of this sort, is gently joggling the uterus in different directions; the repetition of these little succussions generally produces contraction. If, however, the uterus becomes soft, and the patient complains of sickness, faintness, darkness before the eyes, tinnitus aurium, &c., there is reason to fear that internal hæmorrhage is going on; here a little cold water sprinkled in the face, and a small quan-

tity given to drink, or a cold wet cloth applied to the external parts of generation, or upon the abdomen if necessary, will seldom fail to produce a sufficiently powerful contraction of the uterus. Hence, as I before said, gentlemen, our first act, after separating the child, should be, to ascertain if the uterus be contracted; our second, to ascertain whether it remain so.

Many years ago, a most unfortunate case occurred to the celebrated Boer of Vienna, from not having sufficiently attended to whether the uterus remained contracted. He had just returned from a journey made at the expense of the Austrian Government, during the reign of the late Emperor Joseph II., during which he had visited England and France, and had particularly attended the Schools of Midwifery in London under Dr. Denman and Dr. Osborn. On his return to Vienna in 1789, he was made Accoucheur, and, what we should call here, Serjeant-Surgeon to the Imperial Family, besides being appointed Professor of Midwifery, and Chief Physician to the celebrated Lying-in-Hospital of Vienna. In the following year he was appointed to attend the Crown Princess Elizabeth, first wife of the late Emperor of Austria, in her first confinement. She had a long and tedious labour of two days and nights, during all which time, as long as he was in her presence, the etiquette of the Imperial Court required that he should remain standing. You may, therefore, easily imagine how excessively fatigued he must have been. Boer, nevertheless, from his anxiety to prevent even the risk of anything untoward occurring after labour, declared his intention of watching at the bedside of the Princess all night. This she strongly resisted, perceiving that he was quite exhausted with fatigue, and after some entreaty he yielded to her request, and retired into the next room to take some rest. He did not, however, comply, until two of her ladies of honour had promised to watch by her all night, and to call him the instant anything should happen. They agreed to take it by turns; one watched while the other slept, and the princess soon fell into a sound sleep. The lady who watched was pleased to find her mistress enjoying so refreshing a sleep after her long protracted sufferings; she was pale it is true, but how could that be otherwise after what she had undergone? The perspiration stood upon her face and forehead, which the Countess wiped off as gently as possible so as not to disturb her. The Princess breathed hard, and began to snore slightly, but that only told her attendant that she slept. This snoring, however, became less and less natural, until it rather resembled rattling in the throat. The princess was deadly pale, and in a moment after, to the horror of her unsuspecting attendant, became evidently convulsed. A scream from the terrified lady instantly brought Boer into the room, but it was too late, for in a few minutes after the Princess

expired. The bed under the clothes was found deluged with blood; she had died from hæmorrhage. Either from the warmth of the bed, or some other cause, the uterus had ceased to contract, and had become soft, the pressure from the orifices of the uterine vessels had been removed, and they had continued to pour forth their contents until she had flooded to death. This unfortunate event embittered Boer's whole life; it was one of the first cases which he had attended since his return to Vienna; and from the high favour in which he stood with the Emperor, and from the high appointments which he had received from him, there was no want of envious and malicious tongues to invent abominable falsehoods against him. Boer has retired into the country near Vienna, and has never recovered from the shock.

It is an old saying in Germany, that a primipara should not be allowed to sleep for the first twelve hours after her labour. This must not be taken in the literal sense of the word, but rather be applied to her nurse, who should examine the bed, &c., every now and then, to be sure that no hæmorrhage is going on. It is impossible to say when all chance of flooding is gone by. I have seen a case of severe flooding ten or twelve hours after labour; and Professor Naegele informed me of a case where a young lady of rank flooded to death twenty-four hours after delivery. Baudelocque says "I have seen this accident not appear till the eighth day after delivery, and in another case not till the thirteenth. The uterus was soft to the touch, its neck was flaccid, and the hand might easily have been introduced."

Reviews.

Outlines of Comparative Anatomy. By ROBERT E. GRANT, M.D., F.R.S. Ed., &c., &c. *Part I. containing Osteology, Ligaments and Muscles, illustrated with Sixty-five Wood-cuts.* Pp. 144. Baillière. 1835.

HUMAN anatomy teaches the organisation of man, comparative anatomy that of every animal beneath him. In the dawn of medical science, when human dissections were prohibited by the public, and denounced by the priests as impious and offensive to heaven, the votaries of science were, therefore, compelled to resort to the inferior animals for the exploration of living mechanism. It was from these that Galen described his anatomical characters, but when the human body became the subject of dissection, after priestcraft had lowered its head, it was found that between the mechanism of man and brutes, although there was a great and striking analogy, yet there were characteristic indications of their dissimilitude. It would be almost useless, and, moreover, would be foreign to the object of the present review, to tell of the martyrdoms to anatomical science,

how Vesalius, the daring refuter of error, the chief promoter of anatomical research, was vilified as a madman, how he pilgrimaged to Jerusalem, to avert the dreadful inquisition, for opening the body of a nobleman in whom the heart was found still to pulsate. In those days, little was known respecting the structure of the human frame, less was known of the functions of its different parts, and pathology and morbid anatomy slept silent in their tombs.

But during the latter part of the last half century, when almost all Europe was involved in the calamity of war, the torch of philosophy and science seemed as if it had been lighted at the sun for exploring the caves of the earth. Unprecedented was the advance of philosophy; the geologist pierced into the deep recesses of the earth, the chemist discovered the nature of its materials, and the physiologist, by wisely directed inquiries, and by patient observations and elaborate investigations, spread a wide landscape of beautiful phenomena.

John Hunter arose, a bright luminary in the scientific world, who, by a combination of all those qualities which can aggrandise the name of a man and transmit it to posterity, achieved more for the exaltation of medical science than, perhaps, any who preceded him. And there appeared at the same epoch a yet more brilliant luminary in the constellation of physiology—we mean the immortal Bichat. We have, heretofore, paid a small tribute to his memory, it shall not be resumed. Departed greatness shall not be insulted by a repetition of eulogies.

Still human physiology was imperfect; numerous links in the being were in obscurity, or, if perceived, not comprehended. Something more was required. It was necessary to unravel the mechanism of all the living kingdoms of nature, from the algæ which flourish in the depths of the ocean, the sedum which grows on our walls, up to man, vain glorious, yet the perfection of Nature's workmanship. The physiology of plants was studied; their growth, mode of reproduction, habits, and characteristics, were gradually and successively unfolded, and classified into orders. The animal kingdom was resolved into its orders, genera, and species. Linnæus was the creator of the scientific classification of each of those kingdoms; but the improvements in comparative anatomy which have taken place since the very short period of this author's career, is immense, nay, astonishing; it has assumed a new aspect; what was before confused, a wilderness, a chaotic mass, is now all smooth, orderly, and regular, through the united and gigantic exertions of Mickel, Cuvier, Carus, Blumenbach, St. Hilaire, Cruveilhier, Blainville, with a host of others, and "last though not least," *the author of the present work*. Dr. Grant was, we believe, the first in this country who attempted a complete and entire course of comparative anatomy, and with what success he has accomplished his task, the present work affords ample testimony.

We hear it asked almost daily, what is the utility of comparative anatomy?—of what service will it be to me in the practice of my profession? It is said, we think of Kepler, that when once interrogated on the advantages which geometry would afford man, he replied, "to show him that he is a fool." Comparative anatomy shows to the man who knows but human anatomy, that he knows little, if anything, of his subject. That it is by investigating the mechanism of the lower animals we have become acquainted with the same structures in man, requires no ghost from the grave to tell us; the modern writings furnish a sufficient commentary.

But to the work before us. The author commences it with "General Observations on the Osseous System of Animals," and he remarks, that as animals have, generally speaking, either to roam on the surface of the earth, in the liquid stream, &c., a solid support was necessary to sustain the machinery of their carcasses, and upon which the locomotive organs should be enabled to play.

This solid support may exist in the form of a skeleton, placed within the soft parts of the animal, or in the form of a shell, encasing it around, and thus having the soft parts in the interior, the density of this skeleton, or the shell, as well as its complexity, varying in different species as well as in different classes of animals, according to the peculiarity of their habits, localities, &c.

In every class of the animal kingdom, the author remarks, is found a skeleton, more or less compact, though not truly in every animal. As an example, may be adduced the polygastric animalcules, which possess only "an exterior, firm, elastic covering, which protects the more delicate internal parts. This covering sometimes consists only of a more condensed form of the common integument enveloping every part of the body; in others it forms a distinct thin pellucid sheath, into which the animal can withdraw its soft parts for protection."

The present work does not admit of an analysis; our remarks upon it can only be general, and our extracts from it few in number.

The osseous system of every tribe of animals beneath man is fully described, and every part, a description of which cannot be accurately conveyed in language, is faithfully represented by neatly executed wood-cuts.

Skeletons of the different classes of animals are drawn so as to give a fair outline of the bones.

The "Chapter Second" is on the "Organs of Attachment, or Ligaments." It is concise, but contains a large quantity of matter in a small bulk. We shall present a part of its substance. Every bone of the skeleton, whether it be contained in the interior of the animal, or exist upon its surface, is united to its neighbouring ones so as to preserve them in apposition, and to facilitate the freedom of

their motions upon each other. The ligaments, the cartilaginous coverings of bone, and the bones themselves, are endowed with a low degree of vitality, and this deficiency, or lowness of vitality, is obviously dependent upon the scanty supply of blood-vessels and nerves; in proportion just is their sensibility. This is a broad principle, a maxim which future physiologists will receive as a truism. The various modes in which the pieces of the skeleton are united, are graphically described; some, as the higher order of animals, have ligaments, cartilages, fibro-cartilage, and synovial membranes; the ligaments in those classes are firm, dense, and resisting, and are so disposed as to prevent displacement of the bones in the directions they are liable to occur. The cartilages are thick where they invest the centres of convex surfaces, and thin at the margins, where they line cavities, thin in the centres, and accumulated at the margins; in all cases the fibres are arranged in the axes of the limbs.

“In the lowest tribes the component pieces of the skeleton are held together by the simplest mode of union, they have not their points of contact protected by a layer of soft cartilage, lubricated with synovia, and connected by capsular ligaments and internal ligamentous bands, they are partially, or entirely, imbedded in a common, tough, connecting matter, which, by its elasticity, admits of the few required motions. No articulations or ligaments appear in the soft gelatinous transparent bodies of the animalcules, but in the poripherous animals the dense silicious and calcareous spicula, which compose their solid framework, are supported and maintained in their positions by a more tough, elastic, and firm portion of the general cellular tissue of the body, perhaps stimulated to condensation by the presence of these earthy crystalline bodies. By the motions of the body, produced by external bodies, the points of these sharp spicula are made to project from this tough connecting matter in various directions in the gelatinous surface of the body, from the margins of the pores, or into the internal canals. The tubercular filaments in the horny species anastomose with each other freely throughout the whole body, like the continuous connecting matter in the earthy species. The jointed appearance seen in most flexible tubular keratophytes, as *sertularia*, *plumularia*, *campanularia*, is confined to the exterior covering, and does not interrupt the course of the fluids circulating through the enclosed fleshy part. These thinner portions and annular strictures of the horny covering allow of the more ready development of new branches, cells, or vesicles, and of the incessant movements of all their parts, produced by the ever restless sea. The branches of the *collaria thuyra* drop off regularly from below upwards along the stem, at these apparent joints. The minute calcareous spicula of many corticiferous and fleshy zoophytes, as *gorgonia*

and *lobularia*, are connected by the general cellular substance of the body. The black, flexible, elastic matter deposited in concentric layers between the calcareous internal solid pieces of the *isis hippuris*, are merely uncalcified portions of the common animal matter which prevades the whole skeleton, and connects all its earthy particles, they are like the uncalcified portion of *corallina*, but are secreted, as the calcareous matter of the skeleton by the enveloping fleshy crust. The exterior sharp spines of pennatulæ are connected and moved by the coriaceous irritable skin of the body. The skeletons of zoophytes, as those of the higher testaceous animals, are insinuated into the minute inequalities of the surface of rocks, and thus adhere firmly, by being exuded in a soft semifluid state, and then condensing.”

“CHAPTER III.—On the Muscular System, or Active Organs of Motion.”—The muscles are the agents by which we move to and fro, by which voice is produced, and all the voluntary actions are performed. What are the agents of animal motion?—We reply, muscles. What is the character of muscles?—A series of fibres arranged in a parallel direction, each fibre being composed of a series of globules, agglutinated or united together by some plastic yet unknown power—undiscovered property. Do all animals possess the faculty of motion?—Unquestionably they do. Does the same linear arrangement of particles, of globules, obtain in every animal?—Dr. Grant and other comparative anatomists say no. He says,—“In the lowest tribes of animals, in which the slowly irritable fleshy substance appears as a soft, homogeneous, cellular tissue,” all linear arrangement is imperceptible, being lost, nothing appearing but a soft, homogeneous substance, in one animal presenting all the condition of interlaced, web-like, cellular tissues, in another a mere pulpy, gelatinous mass; yet all have motion—all have the interesting prerogative of being capable, if not of roaming abroad, yet of active mobility.

The connexion between the muscular vigour of an animal and the energy of its respiratory function is next discussed. The more vigorous the animal, the more rapid or the more perfect is its respiration. This is a truism no one will doubt. The present part is concluded, we presume, in the middle of the subject of muscular phenomena. It is an interesting subject, and fraught with delightful circumstances.

We have thus much noticed the work before us, and the interesting topic upon which it treats. It now remains for us but to observe on the merits of the first part of this work. In doing so, our comments shall be devoid of partiality—shall be free as air. Comparative anatomy is a branch of science which may be made highly fascinating to the public, and attractive, interesting, and useful to every member of the medical profession. It admits of all the captivating ornaments of rhetoric—

the effusion of imaginative language; but, on the other hand, it should not be obscured in pedantic, verbose, and elaborate phraseology. These observations the learned author will no doubt read, and we believe with advantage, if not to himself, to his work. Few men understand comparative anatomy so well as Dr. Grant; few have the same power of combining the apparently heterogeneous materials which compose the science; but we must confess our opinion, that no one could have made the subject less interesting, less attractive. The language is powerful, and sometimes approaches to eloquence, but too frequently it is verbose; sentences are filled which, though they may please the ear of some by sacrificing the sense, will often offend the judgment of the few.

Nevertheless, even with this fault, the work is excellent. It will be read, however, only by those who are previously acquainted with the subject; we pretend to be so, though we do not teach this branch of science. A student, a tyro in science, would derive little benefit and much less interest from the work; it is too much on the advance of the present day; future ages will accord its merits.

A Treatise on Headachs, their various Causes, Prevention, and Cure. By G. HUME WEATHERHEAD, M.D., &c. &c. Highley.

THE present little work is dedicated to one of the greatest naturalists of the present day, Geoffroy St. Hilaire, as a tribute of esteem which the author entertains for that individual.

When we say that headach is one of the most frequent and troublesome maladies to which man is liable, we shall have the sentiment echoed by the whole profession. It is a disease erratic in its nature, and so untractable, that though one mode of treatment may succeed in one case, in another apparently identical, the same measures will be like throwing chaff to the wind. The Protean-like character it assumes, the shades of difference it presents, render it an intangible, an uncertain disease. Above all other complaints, perhaps, it puzzles the ingenuity of the practitioner. If Dr. Weatherhead has unravelled even some of its intricacies he will have performed a great achievement. Whether he has done so or not remains to be determined by the reception and appreciation of the work.

The work is prefaced by some general observations on the circulation of blood through the brain, the nature of its machinery, the growth, development, &c., of the various parts of the brain are alluded to, its relative sizes in individuals of different countries are discussed, in which the sentiments of the author accord pretty nearly with the accredited doctrines of the day. Instinct and intelligence are adverted to, and their difference shown.

In the 1st section is examined the nature of "Dyspeptic or Sick Headach;" 2nd, of

"Nervous Headach;" 3rd, of "Headach from fulness of Blood;" 4th, of "Rheumatic Headach;" 5th, of "Arthritic Headach;" 6th, of "Headach from Organic lesion;" and, subsequently and lastly, are given the "Rules and Observances for the Prevention of Headach; Clothing, Exercise, Diet, Early Rising, Obviating Habitual Constipation, Regimen of the Mind, Effects of Travelling." Each topic is treated upon in a very lucid and scientific manner. We have been highly interested with its contents: it is assuredly the very best treatise on the subject, and should be read by every one affected with headach, inasmuch as it tells what measures should be adopted for the removal of the malady, and how to avert its aggression.

Report presented by the Council to the Sixteenth Anniversary Meeting of the Hunterian Society. 1835.

WE have been highly gratified with this Report. Its objects and utility are unfolded in the preface; it is to present the Members of the Society and the Profession with a concise yet perspicuous outline of the results of the proceedings during the preceding year. The advantages of those societies are incalculable,—varied talent and experience are brought to bear upon one point. The abstract of the cases presented to the society and of the essays read is of considerable interest. We shall cull a few of them for the benefit of our readers:—

"*Nervous System.*—A paper was read on the distribution and functions of those nerves said by Sir Charles Bell to derive their influence from the tractus respiratorius. The author adverted to the fact, that the sympathetic nerve is formed before any other part of the foetal animal, so that at birth the functions of assimilation, circulation, secretion, respiration, and voluntary motion are under its government. The author endeavoured to show that the precise central origin given to the respiratory nerves does not exist, but that the peculiar powers of those nerves are derived from their connexion with the sympathetic. An interesting discussion, in which some experiments and physiological observations were adduced, in corroboration of the author's opinions, ensued on this communication.

"*Heart.*—instance of hypertrophy of, with ossification of the mitral valves. In this case there was pulpiness of the mucous membrane of the stomach and bowels, and a loaded state of their vessels, which, with some suspicious circumstances preceding death, led to an apprehension of poison. It was shown, however, that such appearances in the alimentary canal are not unfrequently observed after death from disease of the heart.

"*Heart ruptured.*—several instances alluded to, in some of which the patients lived twenty-four hours. In others death was instantaneous. The rupture most frequently happened in the left ventricle.

"Aortic valve,—instance of its rupture in a boy, from his being frightened at the report of a pistol. He instantly felt pain at the region of the heart, soon became dropsical, and died in a year and a half.

"Lungs,—a paper was read on the question whether the parenchyma of the lungs, or the lining membrane of the cells, is the seat of pneumonia. The author believed that what is called inflammation of the substance of the lungs, or pneumonia, is not inflammation of the parenchyma, but of the membrane lining the cells. Also that the inflammation is of two kinds, the plastic and non-plastic, with intermediate varieties. In the former, organised lymph is thrown out; in the latter there is a grey secretion, which gives the diseased portion the name of grey hepatisation, and is much like Castile soap. The products of this inflammation are unorganisable. These two conditions are said to differ, *ab initio*, and to require different treatment—the plastic bleeding and mercury, and the non-plastic stimulants.

"Intestine,—case in which the duodenum was perforated by an ulcer. The patient had resided in warm climates, and was attacked two hours after supper with acute pain in the epigastrium, and about the right shoulder. There was scarcely any affection of pulse. The contents of the intestine and stomach had escaped. The differences between rupture and perforation were alluded to. It was stated that in rupture the mucous membrane invariably curls over the rent peritoneum, but in ulceration the lesion of the mucous membrane usually extends beyond that of the serous. Ulceration of the bowels was considered of frequent occurrence in persons who resided in hot climates. Rest and opium were considered to afford the only chance of closing the opening, whilst the inflammatory stage is to be relieved by venesection.

"A few cases of ulceration of the duodenum were mentioned, in which obstinate vomiting had preceded death. Other instances were related in which the adhesive inflammation had limited the effusion.

"Intestinal hæmorrhage,—with immense discharges of muco-purulent matter.—A case was related in which alum injections, and acid astringents by the mouth, had been serviceable.

"Liver,—a large hydatid cyst of, was exhibited to the Society. The female from whose body it was taken was sixteen years of age. It had been several years in formation, and hæmorrhage from the bowels took place before death. The cyst was attached to the right side of the liver. Its outer covering was formed of the peritoneal coat of the liver, and within this was a second cyst which contained three hydatids.

"In another case a young woman had enlargement of the right side. At length she began to expectorate small hydatids, tinged with bile. This expectoration continued for three months, and then she recovered.

"In another instance small nodules were felt over the hepatic region. They disappeared by purging. It was supposed that they were hydatids, and had passed by the biliary ducts.

"The question of treatment involved considerations as to the safety of tapping, or of opening the cysts more freely. By some it was thought tapping would hazard great constitutional irritation, and, perhaps, suppuration and sloughing of the sac. When these cysts are near serous cavities, it was considered as, usually, better to let them alone, unless a free exit can be given to them. A case, however, was related of the successful removal of three quarts of colourless fluid from an hydatid cyst by trocar. The patient was greatly relieved for a year and half. Then came on cough and expectoration, and he died. The liver was changed into irregular clumsy masses, so that with its greatly thickened peritoneum, its natural character could not be discovered. It was converted into two thick cysts, containing very numerous large and small hydatids, the lower cyst was firmly contracted on several dead hydatids, and in the upper cyst there were numerous living hydatids. This upper cyst communicated, by an aperture through the diaphragm, with the right lung, where there was a large abscess containing shrivelled hydatids.

"It was mentioned that spontaneous cure sometimes occurs. The hydatids shrivel up, the cyst contracts, and remains dormant unless inflammation be excited, when the whole cyst may slough. Two fatal instances of this nature were adverted to.

"Could it be ascertained that adhesion had taken place, it was thought it would be safe to open with a scalpel.

"The importance of correct diagnosis was pointed out, and in aid of this it was mentioned that the specific gravity of the fluid of ascites is to that of hydatids as 1014 to 1001, and that the fluid of hydatids contains no albumen.

"*Veratria*,—some cases in which it failed to give relief, others which it had aggravated, and some in which it had proved beneficial; but the concurrence of testimony was, that its powers had of late been unduly extolled.

"*Colchicum*,—an extract of the acetate was mentioned as deserving of high commendation; and the powder of the root, in doses of five grains, was reported as an efficient form of the remedy. The addition of quinine had been found available, when either apart had not succeeded.

"*Iodine* was brought under observation as a valuable remedy in secondary syphilis, and in affections of the skin and throat where mercury cannot be used. In one case of two years' standing, the utmost advantage had resulted from one grain of iodine and ten of hydriodate of potash, with sarsa, twice a day, for a month."

FOREIGN MEDICAL LITERATURE.

REVIEW OF THE GERMAN JOURNALS.

1st. *Death in consequence of Fasting.*

BY PROFESSOR DE WALTHER.

THE Professor of Munich reports a case of a man, 29 years of age, whom he attended for amaurosis, and who was afterwards under the care of an individual who undertook to cure him by fasting. M. W. B. de D— for some weeks took no solid food whatsoever, and nothing but water, except an occasional cup of tea. His body, weighing before this treatment 130 pounds, was speedily reduced to 97, and to a state of complete emaciation. He died of nervous apoplexy, without having been cured of his amaurosis.

Post Mortem Appearances.—Total want of blood; secretions serous and bilious, regular; between 8 and 10 ounces of serum in the pericardium; the lungs dotted with a great number of tubercles, some of which were approaching a softened and ulcerated state; no inflammation in the intestines, which were contracted and shrunk throughout their whole length, especially at the transverse colon; all the organs of the chest and abdomen in a state of atrophy; the brain and spinal marrow were healthy.

2nd. *On Tumours of the Larynx.*

BY PROFESSOR ALBERS DE BONN.

Hydatids.—The greatest number of cases of hydatids of the larynx admitted by the ancients, and those specifically described by Ploucquet and Lentin, cannot be other, in fact, than œdema of the larynx. Cases of true hydatids are reported by Aubertin, *Essai sur l'Ulceration du Larynx, Journal de Médecine*; Otto, *Handbuch der Pathologischen Anatomie, Breslau*; Delormes, *Journal Générale de la Société de Médecine*; Harless, *Neues Journal der Ausländischen Medicinische, Chirurgischen, Literatur*.

3rd. *Encysted Tumours.*

One case only exists, and that is reported by M. Albers, in his Monography; the fact is curious, and proves the benefit to be expected from laryngotomy. Polypi are frequent; reported cases are given by Zwinger, Morgagni, Lieutaud, Herbiniaux, Desault, Voigtel, Otto, Wendt, and Prinz, in *Wöchentliche Beiträge der Medicinischen und Chirurgischen Klinik*, and by Drs. Clarus and J. Radius. M. Urner gives the following report as taken from M. Albers.

Joseph T—, a joiner of Bonn, aged 54, was in childhood affected with swelling of the glands of the neck, which subsided, and by a dry cough, which continued. Eleven years ago, after a fall, inflammation and hepatitis succeeded. These symptoms, except the dry cough, disappeared by antiphlogistic treatment,

and were followed by sanguineous expectoration, vertigo, pains in the frontal bone, general weakness, and, above all, great suffering under the left clavicle. Bleeding and Seltzer water with milk.

In the course of a few weeks he was able to pursue his employment, but six months afterwards was suddenly seized with swooning and spitting of blood, nearly seven pounds within the space of three days. Bleeding and common salt. The hæmoptysis ceased, but the following symptoms appeared; cough increased; expectoration yellow, abundant, and purulent; agitation; loss of strength; pains in the neck; voice hoarse. Three weeks afterwards he attended the Clinique at Bonn, his state thus:—hæmoptysis habitual; the neck long; larynx very protuberant; the colour of clay; aphonic; pain on pressure of the larynx and when speaking; exterior configuration of the neck normal; cough very frequent, with a hollow sound; sanguineous expectoration, yellow and foetid; respiration very short and difficult; no sound of it under the left clavicle, but sometimes a hollow rattling, and a bawling cry when speaking; urine copious and clear; pain sometimes in the lower region of the abdomen, which yielded to the salt; scarcely any appetite, but an inclination for acid aliment; pulse frequent; feet œdematous and painful; skin burning; sleep tolerable; general wasting of the flesh; an issue in the arm.

An abscess in the upper surface of the left lobe of the lungs was prognosticated, inflammation with exudation of the glottis and larynx, and inflammation of the intestinal mucus. To cupping, cataplasms on the abdomen, mucilaginous drinks, infusion of digitalis, and hydrocyanic acid, the most alarming of these symptoms yielded; a seton was then made at the base of the larynx.

July, 1830, all the symptoms, except pain of the larynx, reappeared, and again yielded to treatment. During the interval, the patient suffered the issue and seton to close. July, 1830, cough very frequent; respiration difficult almost to suffocation, with a sensation of stoppage in the tracheal artery; no pain in the larynx; nocturnal sweats. A blister on the chest, with hydrocyanic acid, lessened the difficulty of respiration, and by October it was overcome, after hæmoptysis. Acetate of lead and an infusion of the seeds of water hemlock, which had before been tried, had no effect; an issue on the chest was made.

February, 1832, the symptoms returned with augmented violence, joined to a difficulty in swallowing, and a pain near the left projection of the os hyoides, pectoriloquy, though indistinct, might be heard as low as the breast; expectoration excessively copious, flowing, and purulent; and thus augmenting and diminishing the symptoms continued until March, when the patient died.

Post Mortem appearance.—Nothing abnormal in the cavity of the skull; the mucous

membrane of the larynx was of a greyish appearance, dotted, chiefly at the proximity of the glottis, with a great number of little lymphatic glands, tumefied, round, and whitish; larynx very large; between the two lower ligaments of the glottis was a small, round, fleshy tumour, about the size of a nut, hard to the touch, and adhering by a root to the cordivocale; immediately behind this tumour, and between the Morgagni ventricles, which were more separated than usual, was a hollow that, forming a partial receptacle to the tumour, lessened the obstruction in the glottis; the right ventricle almost entirely effaced, the left contracted, but still visible; the inferior ligaments of the glottis specially distended; the mucus surrounding the tumour near the glottis partly tumefied and thickened, partly covered over with little ulcers, presenting an appearance as if gnawed; the lower part of the larynx and tracheal artery sound; the thyroid cartilage partly carious near the hollow behind the tumour; thyroideal gland larger, and its lobes more developed than usual; pharynx and nerves of the neck sound.

Lungs.—An abscess in the upper part of the lobe of the left lung; tuberculous granulations in the right; abdominal viscera healthy, except the kidneys, a hydatid being formed in the cortical substance of the right, the size of a small egg, and on the surface of these organs were three hard tumours, partly sunk in the parenchyma, and internally resembling scrofulous glands.

4th. *Spongy tumour,*

Of indeterminate character, affecting a woman forty years of age, and much addicted to drinking and venery. The malady was of three years' duration, characterised by dyspnoea, which continually increasing ended in suffocation and death.—*Archives G n rales, August, 1821.*

5th. *Medullary Sarcoma.*

The following case, by Dr. Tortual, was first inserted in a Report on the State of the Anatomical Institution at Munster during the year 1830, and published by Professor Wutzer.

L—, an ecclesiastic, sixty years of age, complained, November, 1826, of a distressing sensation in his throat (supposed to be an affection of the larynx), accompanied by hoarseness and a cough, especially troublesome when speaking. Spirituous liquors, of which he was very fond, caused a burning sensation in the larynx; respiration tolerably free; fever towards night; emaciation; blister on the neck.

Inobservant of the prescribed diet, the patient was found, January, 1827, by Dr. Tortual, in the following state, with a hoarseness, which, eight days before his death, ended in aphony; pungent sensation in the region of the great cornu of the os hyoides, which was tumefied, and, when swallowing, he felt as if a pointed bone was sticking there;

this sensation, at times became insupportable; and, after coughing, the discharge was purulent.

Fourteen days before death the cough became convulsive, like the whooping-cough, and every minute threatened suffocation; it was generally increasing towards night, especially when lying on his back; the pungent sensation remarkably acute when swallowing anything solid, which he did with extreme difficulty, and it always provoked the cough, so that liquids were all he could take for some days preceding his death; at length he died, suffocated in a fit of coughing.

Post Mortem Appearance.—A medullary sarcoma, the size of a small nut, in the interior of the larynx, between the thyroid cartilage and os hyoides to the left and the epiglottis above the thyro-hyoid ligament; an opening led from this ligament to the tumour, part of which was filled with pus, the mass of the tumour was encephalous; the epiglottis and thyroideal cartilage were pushed away, the mucous membrane of the larynx ulcerated, and covered with a quantity of ichorous pus, and part of the Morgagni ventricles on the same side were equally ulcerated and, as it were, denuded.

6th. *Tumefied Lymphatic Gland in the Larynx.*

REPORTED TO DR. URNER BY PROFESSOR WUTZER, OF BONN.

W—, of Poesfeld, sixty-six years of age, had for some time experienced great difficulty in swallowing; solid food, in passing through the larynx, occasioned great suffering, nor indeed could it pass at all until it had undergone prolonged mastication; he became very thin; nothing abnormal could be discovered on examination of the mouth and oesophagus; exteriorly on the left side of the neck, at angles with the lower jaw and down to the clavicle, was a range of lymphatic glands, very much swollen, and large enough to press on the oesophagus and impede deglutition, caused, it might well be, by brandy, to which the man was much addicted; no trace of gout, syphilis, or scrofula.—Extract of water hemlock, sulphur of antimony, decoction of sarsaparilla interiorly, plaster of water-hemlock on the neck; these, continued for some weeks, caused some amelioration; he could swallow well masticated food without any great difficulty, but about a month afterwards an inflammatory fever took him off in the course of five days.

Post Mortem Examination.—Abdominal viscera sound; lungs adhering in many places to the costal pleuræ, gorged with deep black blood; tissue sound; in the valves of the aorta, and in the aorta itself, osseous depositions of different sizes. On the left side of the neck lymphatic glands tumefied and changed into sacs, filled with a yellowish viscid pus, the largest was found under the sterno-cleido-mastoideal muscle, and adhering, by means of a thickened cellular tissue, to the carotids and inner jugular

vein. The soft glands extended so far into the mediastinum that the last lay behind the second and third ribs, none of these glands could possibly press on the œsophagus; but an inspection of the pharynx quickly discovered the cause of the dysphagia; a softened lymphatic gland, the size of a small nut, was so adhesive, by means of the thickened cellular tissue of the right arytenoid ligament, that it entered the internal cavity of both larynx and pharynx, and of necessity caused impediment to the deglutition of solid food, which was thus compelled to pass over the tumour. It was remarkable, that his voice had continued clear, and his cough only that incidental to drunkards.

7th. Scirrhus and Cancerous Tumour.

We have yet no data from which we can prove the primitive development of scirrhus in the larynx; the tumours found in that organ having, it may be said, originated in the pharynx and œsophagus. Most of the cases, transmitted to us by the ancients, are, even by themselves, considered doubtful, so is that of Smyth's and Morgani's, both evidently of laryngeal polypi; but the latter has reported a case of real scirrhus of the pharynx, which had reached the laryngeal cavity; it is given by Lieutand from Valsalva. Otto cites an observation of Rudolphi's (*Historia Entozoorum*) relative to a scirrhus of the larynx, concerning the nature of which even the latter has a doubt. In fact, the anatomical disposition of that organ can scarcely predispose it to that sort of affection.

8th. Cartilaginous Tumour.

A case of this remarkable affection, developed simultaneously on the exterior of the neck and interior of the larynx, is given by Mr. Macilwain.—*Edin. Medical and Surgical Journal*, vol xxxv. A woman, between 50 and 60 years of age, exhibited all the symptoms of a diseased larynx; respiration difficult, almost to suffocation; thyroïdeale gland tumefied; a tumour on the right side of the sternocleido-mastoïdeale muscle. After all remedies had in vain been tried internally, Mr. Macilwain, with Drs. Houilly and Kington, resorted to tracheotomy. The incision in the neck discovered the branches of a large artery, the trajet of which was so small that there was scarcely an inch of space for the operation, it was therefore abandoned, from the difficulty of its execution in a space so narrow, and because the artery must have remained after the operation on the edge of the suppurating surface. She died of suffocation.

Post mortem appearance.—A tumour in the larynx, hard and almost cartilaginous, so closed up the glottis, that it is wonderful how respiration could be performed through a space so contracted as it left. The extraction of this tumour discovered a small cavity which communicated with the second tumour on the exterior of the larynx, and joined the left lobe of

the thyroïdeale gland; the artery seen at the beginning of the operation was the arteria innominata.

The above fact is a very convincing proof that in certain cases of diseased larynx, laryngotomy ought to supersede every other mode of operation; had it been resorted to instead of decosting, it would certainly have been successful. M. Albers points out a circumstance which often arrests the progress of this disease without having recourse to laryngotomy, namely, the tumefaction of the thyroïdeale gland, which is a general accompaniment of chronic affections of the larynx; the longer the malady endures, the greater the swelling.

9th. Verrucoid Tumours.

A physician of Belgium reports the following fact to Professor Wutzer, who communicated it to Dr. Urner. An architect of Liege, 40 years of age, of robust constitution, was affected with such difficulty of breathing, as to leave no doubt that there existed disease of the larynx. Every remedy internal and external was tried in vain. Dr. Brauers, assisted by M. Baud, Professor of Surgery at Liege, and Dr. Boersbrok, then performed the operation of laryngotomy: an incision being made anteriorly from top to bottom in the thyroïdeale cartilage, verrucoid tumours were found, which filled the cavity of the larynx; they were cauterised with nitrate of mercury. After the lapse of some days, the tumour had so much increased, especially where it had been touched that respiration was extremely difficult; the wound nearly closed; enlarged the wound, and extracted a fragment of the thyroïdeale cartilage. At length red-hot iron was used, which caused only slight inflammation of the interior of the larynx, but behind it was so acute as to prevent his swallowing a drop of liquid for three days. The inflammation subsided, but from the repeated irritations the larynx became one scirrhus mass. Acute hectic fever succeeded; and, though he is still living, no doubt can be entertained of its ultimate result.

10th. Other rare Tumours.—Calculi and Concretions almost unknown. (*Aubertin loc. cit.*)

Great attention should be given to exostoses, which, though rarely developed in the laryngeal cavity, are yet commonly found on the rim of the thyroïdeale cartilage, ascend towards the pharynx, and occasion difficulty of deglutition.—*Albers, Pathologie und Therapie der Kehlkopfkrankheiten. Leipzig, 1829.*

MARCH OF CONSERVATISM.

A WELL informed correspondent informs us that the Governors of Guy's Hospital have lately become so alarmed at the progress of liberal principles, that they have determined to exclude from the governorship all who are not decided conservatives. The present Pre-

sident, a Mr. Samuel Thornton, who has already a number of relatives governors, possessed of the proper Tory qualification, has proposed another member of his family. It is understood that the Right Hon. Secretary for the Home Department (Mr. Goulburn) is also to be proposed. This introduction of politics into charitable institutions deserves notice.

THE

London Medical and Surgical Journal.
Saturday, March 14, 1835.

OBSERVATIONS ON THE NEGLECT OF GOVERNMENT WITH RESPECT TO EMIGRANTS, IN NOT PROVIDING THEM WITH MEDICAL AID DURING THEIR PASSAGE TO OUR COLONIES.

WHILE the iron of Medical Reform is heating in the furnace, and preparing for the hammer of legislation to mould it into the best fashion, it appears to us, that they will most serve the general cause who expose to view, as soon as detected, any abuse having relation to the public health, since in it the profession are interested. In this way, by the contributions of many, a store of the trashy laws and regulations, which now clog and weaken the spring of our utility, will be collected to be sifted and dealt with, when the proper time arrives, as the wisdom of those placed in authority may deem fit. An ample stock of materials is desirable, that the amount of Reform may be commensurate with the necessity for it.

Being convinced of the efficiency of this plan we proceed, in furtherance of it, to offer, without more preamble, a few observations on the evils attending the transit of Emigrants from this country to our different Colonies, and to suggest their remedies. We are further induced to select the present moment as the best for our purpose, from being aware that, as the spring advances, the tide of Emigration will flow strongly from our shores, and give birth anew to the hardships and

calamities so strikingly exemplified in former years;—hardships and calamities so signally inculcating the supineness of the Government which permitted, and the mercenary, heartless avidity of those owners of ships engaged in the traffic, and their no less greedy satellites, certain of the ship brokers.

In order to give a clear view of our subject, we must separate Emigrants into two classes:—one possessing the means to ensure comparatively good treatment by engaging what is called a cabin passage; the other, either very scantily provided with pecuniary means, yet paying for their passage, or, a shade worse, shipped off as paupers at the parish expense; these two grades, being in the eyes of the traffickers very little better one than the other, are consigned to the horrors of the steerage indiscriminately. As these are the principal sufferers, and number as thirty to one of those who can afford the luxury of cabin accommodation, they demand our principal attention, and call most loudly for the sympathy of the philanthropist, and the protection of the legislature. Upon certain risks and dangers which affect all alike, embarked in the same vessel, such as its sea unworthiness, &c., we will not dwell, but proceed to give a brief description of the mode adopted by the caterers for Emigrants to ensure that first of requisites to them,—their health. To be short, then, they do not consult this point, except in a very small degree. Their business, as some of them have expressed it, being to get a shipload of living beings, and something like a ship in which to launch them forth on their dreary voyage. The sum of from 5*l.* to 7*l.* per head, as the case may be, is demanded for a passage in the steerage to Quebec, and this obtained, the matter of furnishing proper berths,

wholesome provisions, and medical attendance is left out of sight, a crime, for neglect we cannot call it, which has devoted, and will yet, if unrestrained by law, consign to the jaws of untimely and wretched death thousands of inexperienced and confiding victims. The passage to any part of our Australian Colonies is conducted upon similar principles of misanthropy and wreckless culpability. All who notice passing events must have learned this fact from the accounts sent home, by surviving unhappy passengers, to this country.

For the instruction of those who have not inspected a vessel, prepared for the purposes of emigration, we give the following sketch of its accommodations, &c.

The speculation being determined upon, a vessel is sought, no matter how crazy, so that it does not actually leak; this is either bought or chartered; if there be already an orlop, or under deck, originally formed to strengthen the ship and separate its cargo (if there be none a temporary and weaker one is built), on it, without more ado, is constructed a range of what are (facetiously?) called berths; these extend generally from abaft the mainmast to the forecabin, or foremost part of the ship, a length varying with the size of the vessel, from forty to a hundred and twenty feet. The berths are formed of deal plank, are about six feet in length, but as for breadth, woefully curtailed, being very little more than the width of an ordinary sized man's shoulders, from point to point. These are arranged in double tiers, so that the uppermost is elevated above the lower about three feet, often less, according to the height between decks. The latter is within an inch or two on a level with the lower deck, and for this reason would, in case of a heavy sea being shipped, when the hatch was left open, be sure of an

effectual swamping; an affair, by the bye, not so easily remedied when sea, as when fresh water is the agent, for the salt being left, after evaporation, in the articles soaked, imbibes afterwards, whenever the atmosphere is loaded with humidity, a portion of the latter, and thus gives rise to many diseases. These tiers of berths, attached to the sides of the vessel, are again subdivided into two *steps*, one about six inches above the other, so that four individuals at least are crammed into a box, consisting of somewhat more than four feet in breadth, six feet in height (at the utmost), and six feet in length.

Into these holes the steerage passengers, at night, or when fatigued, retire. If the weather be fair, and the hatches open, something like a current of air purifies the noxious medium, perfumed with a thousand scents, they breathe; but if, as happens for many days together, upon nearing the North Western coast of America, foul weather should prevail, the hatches are then put down, and the steam arising from so many sweltering bodies, by exhalation from the skin and lungs, pervades the confined space, and poisonous that mainspring of life, the air which surrounds them. Those placed uppermost, in the villainous dormitory, suffer most from the heat evolved, while their undermost companions in misery are more subjected to the deleterious effects of the carbonic acid, thrown off in abundance by the transudation and respiration of so many. If tired of this they seek the deck, their scope of action there bears a strict analogy to that below. From the mainmast to the bowsprit they may travel, that is along the gangways of the vessel, a space always confined and narrow,—on the quarter-deck they must not venture, for *there* exist privileges and

vested rights, the master, his satellites, and the cabin passengers are alone allowed to luxuriate there.

So much for the poor emigrant's lodging; let us take a glance at his board; and here the rapacious wrecklessness of the parties contracting to supply it needs an ample exposure. The provisioning of a vessel destined to this *traffic* of human suffering is limited to the smallest quantity that avaricious calculation can make *apparently* sufficient, for *actual* sufficiency is disregarded (the ship once afloat and on the open sea, responsibility is virtually at an end, or so frittered from owner to master, and from the latter to his petty comrades called *officers*, that security there is none for the living cargo);—we say *frittered* to the smallest modicum capable of sustaining the lives of the passengers during a passage, calculated not at an average, but at the quickest. The stock of provisions is laid in at the lowest estimate,—and such provisions! and managed so adroitly! Until the vessel is at sea a better commodity is distributed; but once upon the ocean, where there is no law but force, no alternative but submission, and the better part of the stock disappears, and leaves either a “hiatus valde deflendus,” or a collection of *combustibles*, for of eatables they deserve not the name, which the poor swindled passengers may well contemplate with dismay,—biscuits decayed and replete with mouldiness and weevil—putrefied provisions in the shape of lumps of decomposed salt-beef and pork which have passed the ordeal of half-a-dozen voyages—the refuse of some paid-off man-of-war—vegetables, none—a scanty supply of water and fuel—and no cooking. These are the comforts which, when he needs them the most, are presented to the astonished and sickened emigrant! Take them he must, or none.

Those who survey a vessel fitted up for the purposes of emigration, before its leaving port, may for a moment admire the neatness and precision of the deal boxes alluded to, fitted up like so many coffins for the reception of their departing friends. *Then*, the smells which will thereafter arise, are not brought into action. A freer circulation of air by means of windsails, &c. *only looked to for the moment*, is kept up. The not unpleasant odour of the fresh cut pinewood is in their noses, and they deem in their innocence that the tarts and cheesecakes they behold will endure for the voyage. But vanity of vanities! nothing can be found more empty. Once at sea, and stiff northwesterers blowing (they blow pretty lengthily, as well as stiffly), and the confectionary of the scene vanishes. Noisome stench, conjured up by the pitching and lurching of the “good ship,” infect the circumambient air. Sea sickness drives into the suffocating steerage, or hold, sufferer after sufferer, and in an incredibly short period its tawdry neatness is converted into the livery of disease, of loathing, and disgust. Add to these disagreeables, the Jack-in-office *hauteur* of the petty louts calling themselves Captains, chief officers, &c., forsooth, the execrable and scanty food doled out, and the picture is sketched; to *paint* it would require an abler hand.

Prepared by what has been said, our readers will not be surprised to know that an address of remonstrance to our legislature, has been forwarded to this country by the people of Quebec, deprecating the further wholesale exportation of ill provided for, half famished, and diseased pauper emigrants to their shores. They complain that, holding out a prospect of gain to them, by encouraging the emigration of able-bodied labourers into their territories (of whom alone they are in

need), we burthen them, under the pretence of so doing, with our sick and diseased; that we have inflicted the visitation of blue cholera on them, and loaded them with the refuse of our parishes. They add that we have shamefully neglected the medical superintendence of our vessels destined to convey emigrants to them, and reproach us deservedly with the consequences.

These are grave charges, and to a certain degree just, and traceable almost altogether, if not entirely, to the deplorable state of the policy of our laws with regard to emigration. Let us examine by what laws the emigrant is protected when, voluntarily or induced by adverse circumstances and the hope of better fortune, he quits his mother-soil. Every one must grant that the die is cast heavily enough against that man whose misfortunes or poverty drive him, without a crime, to forsake the land of his birth. Every one must grant that at his farewell every indulgence, every safeguard which his more fortunate countrymen are able to afford, should be thrown around him as a shield, and the bitter moment of his final divorce from the hearth of his fathers be rendered as palatable, as encouraging as circumstances will permit. Is it so?—Let the impunity with which this class of men have been allowed to be pillaged and fleeced by designing agents and their merciless shipowning principals—let the scenes of disease and death occurring from want of proper restrictions, particularly as respects efficient medical supervision on board the vessels they embark in—let the starvation they endure during and after their voluntary transportation—let the half-sinking wrecks, furbished up for this service in London, Liverpool, and in the ports of Ireland, where life seems to be at a discount, appear in evidence,

answer the question, and shame the legislature.

It is true that, after much mischief had been done, something with the name of an agent was appointed by the government to inspect (we believe at Liverpool, whence the greater number of emigrants shipped themselves) the rickety hulls appropriated for their conveyance; but his vigilance availed nothing; it was evaded, and a more effective blockade upon the operations of the speculators in human life is called for. It is plain that merely inspecting a vessel, and seeing that certain crevices are filled up, and sundry pieces of plank nailed so as not absolutely to choak such as are obliged to sojourn within them, is not all that prudence and humanity require, when a number of passengers of both sexes and all ages are concerned. A proper *medical* inspection before sailing, and *medical* assistance during the passage should be provided. A clear report of the seaworthiness of the vessel should be first made by a surveyor appointed to that duty by government. Following this should come the report of a well-skilled medical inspector, describing the number of passengers, taking into consideration the contingencies likely to occur during the passage, and also the space in height, breadth, and length of the ship, which it might be allowed to convey with comfort and safety, so far as regards health. The next step should be, after the number of passengers is secured, to calculate the amount of provisions necessary, on a liberal scale, allowing for detention at sea from adverse winds, &c.; and, finally, a properly qualified surgeon should be engaged at a settled remuneration, calculated in the compound ratio of the number of passengers and the length of the voyage. The surgeon in this case, as in that

of a convict transport, should have the superintendence; and be responsible for the fulfilment, of certain instructions to be given him on embarkation. The master of the vessel should be charged merely with its navigation.

Under such regulations, a new and satisfactory aspect of affairs would be seen. We should not again hear of a mass of helplessness and pestilence being landed on our colonial shores. Our legislature would be acting that dignified part which becomes it towards the adventurous but less fortunate portion of its exiled subjects, and these, instead of hurling back the bitter reproach which they now do in defiance, would feel grateful that their last parting was one of cordiality and decency. In fact, a large share of bad feeling and enmity would be done away with, and our colonies, and the cause of humanity served.

Doubtless, were an interested ship-owner to peruse such a code of regulations, he would stand on tiptoe to pronounce *his* anathema against them; but shipowners—we mean the sordid class engaged in this villainous traffic—and justice and humanity differ *toto cælo*. Their tricks in this nefarious way it shall be our care to look after in future, and expose as we detect them: for the present we assure them that we are aware of the mean-spirited and paltry manner in which they obeyed the order in council made some three years ago, when the prevalence of cholera induced the government to issue orders that a surgeon should be provided for every ship carrying out passengers. In the first place, they evaded the order as much as in them lay; in the second, they engaged such striplings in the profession and needy half-educated adventurers, as they could persuade to give their service in lieu of a passage

which *they* represented would, at its conclusion, introduce them into a land flowing with milk and honey, but which they found barren and profitless; and, thirdly, when they found that flesh and blood would bear the insult, they petitioned the Government to rescind its salutary order, one of its wisest, and permit them to carry on their trade of disease and death without restraint. All this they did, and more will they do in the same strain, unless bound down to deal as honest men should deal, to give an equivalent for the money they receive from those who entrust their lives to their care.

The nonsense which interested individuals may oppose to the employment of medical men, such as that the remuneration afforded them would enhance the price of passage to the emigrant, is scarcely worth notice. A calculation of the profits arising to speculators in this traffic, would be the best answer. Our limits do not at present allow us to enter into it, but in a future number, perhaps the next, an *exposé* of their receipts and disbursements shall be given to our readers. In the meantime we assert, without fear of contradiction, that, according to the prices they charge, they might afford better treatment of every description, pay a medical superintendent upon the passage, and pocket, after all, enough to induce a more honest race of men to embark in the same speculation.

THE BRENCHLEY CASE OF LITHOTOMY.

WE have, from the first, been in possession of the leading features of this case, which has for the last few days been darkly alluded to by many of the London and country Journals. We, however, did not feel warranted in noticing, or offering any comments upon it, until further au-

thenticated. We have now to inform our readers that an examination of the parties implicated, the Rev. — Arthur, Mr. Monckton, surgeon, and Thomas Russel, master of the workhouse, in which the boy operated upon (James Roberts) was a pauper, has taken place before three magistrates, at Tunbridge Wells. The evidence is now before us, but our arrangements will not permit of our laying it before our readers, or commenting upon it in our present number.

It appears, from the evidence, that the boy Roberts was unwilling that the operation should be performed upon him, that there was much difficulty in getting him to submit to it, and that he showed great stubbornness when ordered into the Committee-room for the purpose.

It appears that Thomas Russel, the master of the workhouse, was desired to fetch the boy: this he did. Subsequently, *four men*, whose names are mentioned, were ordered to *hold the boy down* while the operation was being performed! Mr. Monckton, after making the usual incision, succeeded in extracting, with his finger and thumb, a small *stony* substance about the size of a pea, but very *soft*! Mr. Arthur assisted in the operation.

The magistrates, after consulting together, said they did not consider this to be a question of surgical skill so much as one of assault; but, in order that they might give an impartial hearing, they adjourned the case to the next day. On this day the parish officers of Brenchley attended pursuant to summons. One of the overseers said, he resolved with one of the parish surgeons (Mr. Outeridge) that Mr. Monckton should not perform the operation, as he had determined that a Mr. Hargraves should perform it, Mr. Monckton having failed in a former attempt upon the boy's bladder. This overseer

admitted, *that if Mr. Monckton had not called to see his children he should not have spoken to him upon the subject of the boy's infirmity.* He also admitted, that if the boy had been attacked by any casual illness, he should have considered him under Mr. Monckton's care. He also gave Mr. Monckton and Mr. Arthur a good character. Mr. M. said that he examined the boy, and on finding the stone was in the passage he made an incision, with the hope of extracting it, but it slipped back into the bladder.

One of the magistrates, on behalf of himself and brother magistrates, then addressed the defendants, stating that they fully acquitted them of the charge of treating the boy ill, or of trifling with his feelings; that, as far as Mr. Arthur was concerned, they dismissed the case altogether, but felt it their duty to send Mr. Monckton's case to the Sessions. A serious reproof was administered to the man Russel, Master of the Workhouse, for his dereliction of duty in not protecting the boy, and the different parties were bound down to appear at the assizes on the 17th. inst. We refrain from any comments at present, but congratulate all who are lovers of freedom and haters of undue coercion, that a jury will have to decide the case.

PORTRAIT OF DUPUYTREN.

WE have been favoured by Mr. Renshaw, of the Strand, with the view of a half length portrait of this, not unaptly named by his countrymen, "Colossus of Surgery." It is exceedingly well executed in lithography, from a drawing by the talented Mourier. We had no sooner fixed our eyes on the portrait, than its exact resemblance to the eminent and lamented original, whom we had formerly seen in Paris, struck us. His lofty and expanded forehead, the commanding eye, for which Dupuytren was conspicuous beyond his confrères, and the nobly formed features beneath, are finely depicted by the artist, who seems, in addition, to have caught and delineated with peculiar happiness that expression of indivi-

duality so difficult to paint, but without which a likeness is cold, spiritless, and devoid of interest. By those who admired this truly great man, equally adorned by excellence of talent and unbounded philanthropy, this resemblance will be highly prized. It is a faithful memento of the illustrious dead, fraught with his living characteristics, and ought to have a place in the study of every lover of our profession.

Foreign Medicine.

Function of the Optic and Olfactory Nerves.
M. VIDAL has communicated to the Anatomical Society of Paris, a case of fungous tumour of the dura mater, at the base of the cranium. The optic and olfactory nerves were compressed and destroyed by the tumour, whilst the fifth pair remained perfectly unaffected; vision and the sense of smell were destroyed. This fact confirms certain experiments of M. Magendie, from which it results that if the trifacial nerve is necessary to vision, at least it cannot be considered as the exclusive organ of this function. It also tends to prove, in opposition to the opinion of the celebrated physiologist just alluded to, that the olfactory nerve enjoys the same prerogative as the optic, in relation to the sense to which it transmits impressions.—*Compte rendu des Travaux de la Soc. Anat.*

Amnesia.

M. Cassan has communicated to the Royal Academy of Medicine of Paris, the following interesting case of cerebral disease, with the loss of memory of words. A man was attacked with hemiplegia, which was relieved by bleeding and blistering. Shortly afterwards he experienced incipient amaurosis in both eyes, with pain in the head, and noise in his ears. After some time hemiplegia returned. The patient then lost the memory of words, so that he could not name the most common things; his mind in other respects was unimpaired, and all the organic functions were properly performed; he could also read fluently. He remembered objects, for he drew them upon paper, but he forgot the names by which they were called. The sight of a female whom he loved excited him, and momentarily restored the faculty of language he had lost. He complained of insomnia, heaviness of the head, difficulty of muscular action, weakness of sight, hearing, &c.

This case is analogous to that of the notary, recorded by M. Pinel in his Nosography, who, after an attack of apoplexy, forgot his own name, that of his wife, and of his children, but remembered the places where his clients' briefs were deposited. M. Larrey has also related an instance of the loss of memory of words following a wound. Professor Broussonet has also recorded an instance in which there was a loss of memory of substantives, while that of adjectives was preserved; it followed apoplexy;

and a similar case is recorded by Dr. Cambert in the *Journal Complémentaire* for February, 1819.

Foreign Hospital Report.

HÔPITAL DE ST. ANTHONY.

Case of complete absence of the Cerebellum, together with the Posterior Peduncles and Protuberances of the Cerebrum, in a Young Girl who died in her 11th Year.

Alexandrine Labrosse was born at Versailles, in May, 1820. Her father was of a strong and robust constitution, her mother, on the contrary, was a weak and unhealthy woman, and accustomed to excesses of every description. When born, the child was extremely feeble, but well formed; she continued extremely delicate and puny, and grew but slowly. At two years of age, she had not cut her first teeth, and it was not until she was three years of age that she could lisp a few words. M. Miguel, who communicated these particulars, saw her for the first time in 1829, when he was informed by her father that she was five years of age before she could stand alone. He was astonished at her small size, and remarked particularly the great feebleness of the extremities. This symptom, joined to the want of intelligence in the child, and the impossibility of her articulating a word clearly, had induced M. Miguel to suspect some injury in the brain. He was several times called upon to prescribe for gastrointestinal irritation, although these presented no remarkable peculiarities. The last time he saw her, which was after her ninth year, he found the pupils extremely dilated, from which he was led to suspect the presence of worms in the intestinal canal. He was about to direct anthelmintics, when the nurse informed him that the little patient kept her hands constantly applied over the genital parts.

On the 12th of January, 1830, she was admitted into the Hôpital des Orphelins, as a forsaken child. Her certificate of admission represented her as paralysed in the abdominal extremities, speaking with difficulty, and that her disease was owing to a fright experienced by her nurse.

In the letter addressed to the superintendent, requesting her admission, M. Miguel observes, "this little girl, although nine and a half years old, in consequence of the poor nourishment and little care she had received, is scarcely as large as a child of six years; this cause has arrested the development of both her physical and moral faculties."

At the time of her entrance into the Orphelins, she was feeble, cachectic, and possessed of very little intelligence. Apparently indifferent to every thing surrounding her, she nevertheless manifested friendship and gratitude for those who rendered her any attentions. When spoken to, she replied with

difficulty and hesitation. Her limbs though extremely feeble, yet allowed her to walk, but she often fell down. She possessed the use of all her senses, eat moderately, and all the functions of nutrition were well performed.

In the month of January, 1831, when seen by M. Combette, her condition was as follows:—Her features indicated a deteriorated constitution, and possessed an air of stupidity; she lay constantly upon her back, with her head inclined to the left side, and she could scarcely move her limbs, which, however, exhibited no diminution of sensibility; she had the free use of her hands; her condition always manifested depression and dulness, and she seemed alike indifferent to both pleasure and pain. When questioned, she replied simply *yes* or *no*, always, however, correctly.

For a long time she had been subject to glandular engorgements about the neck, and especially near the parotids, and for a fortnight had a carbuncle, of no great size or violence, situated on the right buttock. On the three outermost toes on the same side there existed an ulceration accompanied by a livid redness, from which there was a very abundant discharge of extremely foetid pus.

Towards the middle of February, along with her other infirmities, Alexandrine Labrosse had stomatitis (as had many other children in the hospital), complicated with symptoms of enteritis. After this she grew daily more and more feeble, exhausted by an incessant diarrhoea.

She died on the 25th of March, 1831. Since her death, I have been positively informed, that she was addicted to the habit of masturbation. The sisters have also assured me that she was subject to epileptic convulsions, and that a few moments before death she had experienced a violent general convulsion.

Autopsy thirty hours after death.

External Habit.—Body lank and emaciated; skin discoloured; large slough over the sacrum; a small livid wound on the right buttock, occasioned by the incisions I had made. The three diseased toes had a blackish and gangrenous appearance; scrofulous engorgements upon the neck.

Head.—Under the integuments of the cranium near the parietal protuberance of the right side, an echymosis existed about the size of a dollar; the cranium was much thicker than usual; the meninges of the brain appeared healthy; the cerebrum appeared in a natural condition, except that it seemed to me comparatively very large. Dissected subsequently by M. Magendie, a small sanguineous effusion was found in the left posterior lobe, which did not appear to have existed long, and which was not more than two or three lines in diameter. The covering of the cerebellum being divided, the medulla oblongata cut at the occipital foramen, and the encephalic mass raised and inverted, the following appearances were observed:—

A large quantity of serum was discharged,

filling the occipital fossæ. In place of the cerebellum, I found a gelatinous membrane of a semicircular form, attached to the medulla oblongata by two membranous and gelatinous peduncles. The one of these on the right side had been torn. Near these peduncles I found two small white isolated masses about the size of a pea. On one of these was found one of the branches of the fourth pair of nerves. The tuberculi quadrigemini were entire. On the posterior and inferior side there was the appearance of an erosion, in the midst of which the orifice of the canal of Sylvius appeared. It extended a little upon the medulla oblongata, making a slight alteration in the restiform, and in the olivary bodies. The fourth ventricle did not exist. There was no trace of a pons varolii, but without any appearance of want of substance. The anterior pyramidalia terminated in a fork by the cerebral peduncles.

Of the cerebral nerves, I could only find the origin of the first, second, third, and fourth pairs, which appeared in a healthy state, except the latter, which was, as I have said, detached with the small white mass, of which I have spoken. Not having raised the brain myself, it was impossible for me to find the origin of the other pairs. They all, however, existed, and could be easily perceived through the openings of the dura mater. They have, moreover, been subsequently dissected by M. Magendie, and exhibited no peculiarity.

The cerebral substance was of the ordinary consistence, but the medulla oblongata appeared a little softened, especially about the erosion I have described, where there existed a kind of maceration. The occipital hollows were regularly formed, but appeared to me rather smaller than natural. The vertebral arteries existed. I cannot say how these were distributed, because they did not at first fix my attention.

Spine.—A considerable quantity of serum ran from the spinal canal. The spinal marrow offered nothing remarkable.

Chest.—Both lobes of the lungs crepitated, but their whole surface was covered with miliary tubercles, which were also found in the parenchyma. The cavity of each pleura contained two or three ounces of serosity. The pericardium and heart offered nothing in particular.

Abdomen.—The intestinal circumvolutions were of a deep red colour. The mucous membrane of the stomach exhibited a number of red dots on a slate coloured ground, and near the anterior part and great arch, there were five or six brown patches. In the middle of each of these, a small ulceration with elevated and perpendicular borders appeared. This membrane was otherwise of its ordinary consistence and thickness.

The mucous coat of the duodenum presented no ulceration. It was slightly red, and its follicles prominent. After this, throughout the whole tract of the small intestine, it was of

a livid red colour, presenting numerous ulcerations, especially about the ileo-cæcal valve. The large intestines presented nothing in particular.

The mesenteric ganglions were larger than ordinary. The liver was of an extraordinary size, and of a pale colour.

The Organs of Generation.—The finger could readily be introduced into the vagina. The hymen did not exist. The labia were of a lively red colour, and bore the appearance of having been frequently irritated. The ovaries and uterus existed, but they appeared smaller than usual with girls of the same age.

The kidneys, spleen, &c., were in a natural state.

Conclusions.—This singular case is calculated to excite the particular attention of physicians of the physiological school, and presents no less interest for pathologists. I regret exceedingly my inability to say anything relative to the moral condition of this child previous to its entrance into the hospital, and am still in the expectation of receiving further information. Should any particulars be offered, I shall immediately communicate them.—*Bull. de la Soc. Anai.*—*Rev. Médicale.*

ASILE L'ENFANCE.

Catarrhal and Muco-purulent Epidemic Ophthalmia.

BY DR. CHARDON, JUNIOR.

Catarrhal ophthalmia, occasionally assuming a muco-purulent form, has been recently epidemic at the asylum of infancy, in the faubourg St. Germain. Out of one hundred and fifty children of either sex, from three to seven years old, now within the walls of this establishment, which is in a very healthy situation, scarcely any have escaped this complaint, and many have had it a second time.

It was more especially characterised by an abundant secretion of a puriform discharge, more or less thick. The injection of the eyes presented the appearances attributed to the catarrhal, and not unfrequently also those of the scrofulous, injection. In twenty cases, pustules formed about half a line distant from the cornea.

The redness of the conjunctiva was not in proportion with the blennorrhagic discharge, and many of the children had a very free secretion, with scarcely any injection of the conjunctiva.

In addition, the photophobia and the pains were very slight, and vision was good, except in those cases where the cornea was constantly covered with the secretion of pus.

The duration of the disease, which existed nearly three months in the house, varied in different individuals. In one-half the patients it continued in the acute form only about eight or ten days; in others from twelve to fifteen; finally, in the greater number, after remaining acute for the period just indicated, there would

be a slight discharge for a week or two afterwards.

The ophthalmia was severe in some of the children, but in almost all the instances it was confined to the conjunctiva of the palpebra and eye.

A grain of the corrosive sublimate, in two ounces of distilled water, was used as a collyrium. From four to eight grains of calomel, with as much jalap, was given internally; in some cases leeches were applied to the thighs. With such measures the progress of this epidemic was arrested, and in no case did any injurious results occur.

British Hospital Report.

WESTMINSTER HOSPITAL.

Diseases of the Testicle.

CASE I.—*Orchitis.*—James Pigot, ætat. 24, tall and thin, of an atrabilious temperament, was admitted into Percy Ward, Sept. 23rd, 1833, under Sir A. Carlisle. While ascending a ladder his foot slipped, and he fell, striking the right testicle against it. The organ became swelled and painful; twelve leeches were ordered to be applied, to be followed by cold lotion.

24th. Complains of pain in the loins, and increase of pain in the testicle, extending up the cord, with considerable swelling; cannot bear manipulation; bowels open; makes water freely.—Cont. lotio, et habeat haust. cathart.

25th. Slept a little during the night; complains of great pain in the abdomen, pressure on which he says is unbearable; the pain in the loins continues, that in the testicle is lessened, but the swelling is greater; bowels open three or four times during the day; pulse rather full and quick, but not frequent; 80; tongue furred; great thirst.—Applic. hirud. xxiv. testi.

R. Antim. tartariz. gr. ij.; magnes. sulph. ʒj.; mist. camph. ʒvj.; liq. ammon. acet. f. ʒij.—Solve, fiat mistura cujus capiat cochlearia larga duo 2dis horis. Cont. lotio.

26th. The leeches were not applied until the evening; they bled freely, and he is now much relieved; the pain is very much diminished; bowels open.

27th. Has suffered an accession of pain in the loins and testicle.—Applic. hirud. xij. Cont. mist.

28th. Pain much lessened by the leeches, and the swelling appears to be diminished.

29th. The pain has recurred, and the other testicle and spermatic cord are similarly affected; the pain in the loins continues, and she is very feverish.—Applic. hirud. xij. test. sinistro. Rep. mist.

30th. Pain again relieved, and he is improving.

Oct. 2nd. The pain continues to diminish,

and the swelling of both testicles has decreased very much—they are scarcely more than half the size they were.

8th. The pain is quite gone, and the tumefaction continues to lessen; the epididymes remain hard and enlarged.

11th. The swelling has recurred in the right testicle and cord, both of which are painful to the touch; is ordered leeches to the part.

12th. The leeches have not been applied, there not being any fresh ones in the ward. The pain has continued to increase in severity, and has extended to the abdomen and loins as in the previous attack; excessive tenderness of the parts exists.

13th. Although the leeches have not been applied this time, he has experienced more rapid relief than on the previous occasions. He is now nearly free from pain, and apparently doing well.

19th. Is quite free from pain, and the testes are of their natural size.

23rd. Dismissed.

CASE II.—*Orchitis*.—Frederick Gladwith, ætat. 17, a servant, of the middle size, and sanguineous temperament, was admitted into John's Ward, Sept. 25th, 1833, under Mr. White. On the 21st, in the evening, he first perceived a swelling of the left testicle, attended with great pain, so as to prevent his sleeping. He got alarmed at this, and went to a chemist, who directed him to apply eight leeches, to be followed by cold lotion; he also gave him some purgative medicine. He followed this advice, but found no benefit; on the contrary, the pain and tumefaction continued to increase.

On examination, the testicle was found very much swelled, and exceedingly painful, so that he cannot bear to have even the integuments touched; the scrotum of that side is distended and inflamed; the cord is tender; complains of severe pain across the loins; slight scalding of water; bowels very open; pulse more frequent and fuller than natural; no headach.

He says that he does not know any cause for this attack; has never had the clap, nor been in the way of getting it; he has not received any blow or kick, or other injury to the part; the only cause to which he can ascribe it is carrying heavy weights up and down stairs. Mr. W. B. Lynn saw him, and ordered him to keep in bed, and have twenty-four leeches applied.

26th. He continues in much the same state; the leeches have not been applied, and nothing has been done for him; bowels open. Let the leeches be applied at once.

R. Antim. tart. gr. ij.; magn. sulph. f. ℥jss.; liq. ammon. acet. ℥ij.; mist. camph. ℥vj.; fiat mist. capiat coch. larg. ij., secundis horis.—Cold lotions to be applied after the leeches have dropped off, low diet, and to wear a bag truss.

27th. The leeches bled well, and the pain is much relieved, but the tumefaction continues; the medicine made him vomit once, and has kept up a state of constant nausea since; bowels well open; skin cool; pulse regular, not so full as it was.

28th. Mr. White directs the medicine to be continued, with the omission of the ant. tart.

29th. Is free from pain, and going on well.

From this time may be dated the cure of the inflammation; the swelling of the testicle diminished very gradually, and it was not entirely reduced when he left the hospital on the 5th of November.

CASE III.—*Laceration of the Scrotum, followed by Orchitis*.—Elijah Edwards, ætat. 15, a labourer, was admitted into Northumberland Ward, January 6th, 1835, under Mr. Guthrie. Is a pale thin lad, of the strumous diathesis. He states that while ascending a ladder, as he was placing his foot on the twentieth step from the ground, he slipped and fell, striking against a post. A lacerated wound of the scrotum was the result, the testicles being exposed, and hanging out of the wound. He was immediately carried to the hospital, where the testes were returned, the lips of the wound brought into contact, and retained so by ligatures. He was placed on low diet, and ordered salines with tartarised antimony, and cold lotion to the part.

Inflammation affecting the scrotum set in to a considerable extent, for which leeches were applied with some benefit, but it soon extended to the testicle, which became much tumefied and very tender, so that he could not bear to be touched. Thirty-six leeches were applied, and when they dropped off, a poultice was used to encourage the bleeding. The inflammation, although lessened, still continued, and required the further application of leeches; the medicine was given so as to produce and keep up nausea. On the 11th he was cupped on the perinæum with decided relief; by the 18th he was entirely free from pain, and early in February he was dismissed cured.

CASE IV.—*Chronic Enlargement of the Testicle*.—Jacob Button, ætat. 42, a native of Somersetshire, now resident in the Vauxhall-road, was admitted into Mark's Ward, Aug. 8th, 1833, under Mr. Guthrie. Is an excavator, a man rather above the middle size, and stout, sanguineous temperament, florid complexion, not married; has had the venereal disease, he thinks, about twenty times, gonorrhœa only once, and that so recently as a year and a half ago; the left testicle began to swell shortly afterwards, attended with what he considered to be a rheumatic affection of the joints, and symptoms of fever. He was an in-patient in this hospital for that complaint. The swelling of the testicle continued for about four or five months, and as that got better the right became enlarged, attended

with considerable pain and fever. He placed himself under medical treatment, and leeches followed by fomentations, &c., were employed. By these means the swelling was nearly removed, but some induration still existed; in about six weeks after it was again nearly the same size as before: it was much reduced by treatment, but re-enlarged, and continues so; he has never had secondary symptoms of syphilis.

The right testicle is enlarged, elongated, and harder than natural, but smooth, without any irregularities, either in shape or degree of firmness; the cord on the right side is also enlarged, but not hardened, nor does it appear to be otherwise diseased; he suffers very great pain occasionally in that testicle; the left is rather enlarged, but not painful.—Middle diet.

18th. His general health is out of order; he is taking, by Mr. Guthrie's orders, a pill composed of hyd. submur. gr. iss., extr. conii gr. iij., night and morning; has not yet any coppery taste or symptoms of ptyalism; the pain is lessened.

27th. Continues much the same; no mercurial action; to continue the pills, and rub in the ung. hydrarg. fort.

29th. Slight mercurial taste in the mouth, and other symptoms of commencing ptyalism are showing themselves; thinks himself improved, and the pain is diminished.

Sept. 2nd. He is now freely salivated, and the mouth is very sore; the testicle is much smaller.

5th. The testicle is now about half the size it was when he came in.

7th. Mr. Guthrie remarked to-day when he saw him, that in such a case formerly the testis would have been removed on the supposition of its being scirrhus.

11th. Continues to improve; the testicle is nearly of the same size as the other; is to leave off mercury.

24th. Dismissed, with directions to take care of himself.

CASE V.—Fungus of the Testicle.—George Harris, ætat. 24, admitted August 13th, 1833, into Mark's Ward, under Mr. Lynn; is a native of Bristol, by employment a clerk; dark complexion, nervo-sanguineous temperament; says he has always enjoyed very good health; has had clap three times, but says he never had syphilis. He has never had sore throat, eruption, inflammation of the eye, or buboes; he, however, had chancres about nine months ago, which he treated himself with blue-stone, and did not take mercury. Had an attack of gonorrhœa about the same time, which continued on him a month; has never had any blow or other injury to the testes. The tale he tells as to the cause of his complaint is as follows:—About seven months ago, he was sitting on a low wall in his mother's garden, his testes hanging close to the wall, which felt very cold, and which he con-

siders produced the present complaint. Shortly afterwards the left one began to swell, without pain. He had not clap, or other disease, at the time: it was attended with pain in the back, but none in the urethra, nor was there any sediment in the urine. A fortnight after, he became an out-patient at the Bristol Infirmary, having had nothing done for it previously. He was there treated by nauseants, and poultices to the part: by these means, the pain in the back was removed, but the swelling continued. He attended there about a month, and then gave up his letter. The testis was at that time twice its natural size: during all this time he never wore a suspensory. A fortnight, or rather more, afterwards, it ulcerated, and, shortly after, a painless, insensible fungus protruded, not bleeding, or giving pain, even when cut or burnt: he then re-attended at the Infirmary, when he was directed to poultice it, and take opening medicine. In another fortnight, the right testicle began to swell, and speedily ulcerated, still unattended with pain. The left continued in the same state, but the fungus separated from the right organ, and the opening closed, under the application of strapping. This time he attended at the infirmary nine weeks, and, when he ceased going, the left was as bad as ever. Three weeks after he had given up his letter, the right ulcerated again, and a fresh protrusion of fungus took place. He was now induced to come up to town: he performed the journey on foot, and shortly after entered this hospital.

He says his health is good; sleeps well; is not in any pain: the only inconvenience he suffers is from the unsightly and unpleasant appearance of his testicles, the disagreeableness of the discharge, and their additional weight. Appetite good; bowels regular; tongue rather furred; pulse regular, but rather full, eighty beats in the minute. He has not had stricture, and has not any other complaint of the urinary organs.—The venereal desire continues, and he considers that he has quite as much power of gratifying it as before the appearance of this complaint, but, perhaps, less frequently than formerly. The left testis is much larger than natural, and considerably indurated; the fungous growth is irregular in shape, whitish, and indolent, with a secretion of unhealthy pus; the cords feel normal.

He was admitted with the view of performing castration; but, after he had been a little while in the hospital, he made up his mind to keep them, and accordingly left the hospital, which he, in all probability, only entered as a place of refuge to relieve himself from his fatigue.

The result of the next case will show that it is very probable that had an operation been performed, the testes would have been found sound, the fungus springing from the tunica albuginea; the symptoms resembled each other perfectly in both cases.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Saturday, Feb. 28, and Thursday, March 5, 1835:—Alfred Lochéc, —; Edward Joseph Staples, Bristol; John Gorham, Tonbridge; George Tomkyns George, Bath; Geo. Connolly Cone Lunn, Guernsey; Thos. Chandler, —; John Lower Clark, Devouport; Parker Margetson, Kirkby Stephen; John Jackson, Wharfedale, Notts.

MISCELLANY OF FACTS.

Bengeforth, St. Peter, Evesham.—One of the guardians of this parish, elected in 1815, was continued in office for fifteen years. This gentleman united in himself the several offices of *magistrate! guardian of the poor!! surveyor of roads!!! assessor of taxes!!!!* and was, besides, a *medical man!!!!* The utmost number of inmates in the workhouse has been eighteen, the least twelve. They have been fed, clothed, washed for, *physicked*, and kept warm for 614 weeks at 2s. 5 $\frac{1}{2}$ d. a-head each week. It is but justice to add, that this gentleman has reduced the parochial expenditure nearly one-half.

We have just been informed that while a certain celebrated performer of operations upon rabbits in the borough was the other day in the act of executing one of his first-rate cuts, the amazed and horror-struck animal bolted. The gentleman in question gave chase, and pursued the *doomed* at the top of his speed. How long the chase would have continued we cannot say, but thus far our informant states, that the Professor, having made a *demi-volte* on one side to catch his four-footed prey, something or other caught his great toe, and down he fell. The rabbit has not since been heard of.

Proposal to establish a Charitable Institution for affording Medical Assistance to indigent Europeans and East Indians at Calcutta.—Mr. Hutchinson, in a long letter to the editors of the *Indian Journal of Medical Sciences*, recommends the institution of a kind of dispensary for the European poor in Calcutta, because the general hospital is at such a distance from the city as to render it almost useless to send there in cases of emergency. If the government could be induced to allow the prescriptions to be prepared at their dispensary, as Mr. H. seems to expect, it is calculated that the whole expense could not be more than 2500 rupees annually, including the pay of the medical officer, at 100 rupees a month, little enough for the duties Mr. H. proposes, viz.—two hours' attendance every morning and one hour each afternoon.

Dr. Auzoux's Anatomical Figure.—We have great pleasure in stating that, in the course of last year, a copy of this splendid machine was received in Calcutta from the Court of Directors of the Company, and placed in the Native Medical Institution. It cannot fail to be of great service in India, where, from the heat of the climate, it must be almost impossible to dissect.

The annual expense of the medical establishment of the King of the French is 176,000 francs, or very nearly [rather more than] £7000 sterling. Of this sum the first physician has 20,000 francs, the second 12,000, and the remainder of the amount is divided among the physicians, surgeons, and apothecaries of the household.

It has been determined, in the disposal of insane patients (soldiers), admitted into the Military Lunatic Asylum at Chatham, whose services do not give them a claim to be wholly maintained at the public expense, and who, after treatment for a reasonable period, can obtain no prospect of benefit from a further continuance in the hospital, that part of the expense at least shall be borne by their parishes. The admission of female

patients, the wives and widows of soldiers, into the asylum is very nearly stopped altogether, on the ground that their admission appears to be so objectionable in principle as to be justifiable only under the most urgent and extraordinary circumstances.

WEEKLY BILL OF MORTALITY.

London, Tuesday, March 10th, 1835.

Abscess	4	Inflammation	24

CORRESPONDENTS.

Ignis Fatuus.—The Royal Society have the gift of 60l. every other year for any discovery concerning heat and light.

A Subscriber.—The numbers he inquires for may be obtained by application at our office.

Thaumatrope.—The peculiar property of the eye which he describes is more suitable to some work on natural philosophy than to our pages.

Philo-Pharmakos.—The scheme of mutual concession between general practitioners and chemists, we fear, is not practicable: the change would be too sudden.

"Cholera."—The frigate which conveyed the cholera to the Isle of France was the *Topaz*.

The Surgeon of a South Seaman.—His comments upon the formation of the head of a New Zealander are under consideration. The sample he has sent us appears to be extremely well preserved, and we thank him for the specimen.

Tabacus.—We know that some instances have occurred of foreign substances, of which snuff formed the nucleus, being found in the frontal sinuses. We believe it was the late Mr. Joshua Brookes that possessed several preparations indicating the possibility of such an occurrence.

Our correspondent from Quebec will see that we have noticed his communication.

A Lover of Pure Water.—Our Hampstead correspondent shall be attended to in our next, or, at all events, as soon as the press of matter will allow us to consider his views.

H. R. S.—We have long been aware that titillations per anum have procured dejections in the same mode as by the use of clysters.

Nauticus.—There is no regulation compelling ships containing a less number than fifty passengers, crew included, to take a surgeon on board: the law wants amendment in this respect.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

At the Meath Hospital during the Session of 1834-5.

LECTURE III.

Sleeplessness—Sleeplessness from Anxiety, Grief, &c.—Case of Jaundice accompanied by Sleeplessness—Treatment—Remarks on Purgative Mixtures—On the proper time for administering Opiates—Sleeplessness in Delirium Tremens—Chronic variety of Delirium Tremens—Treatment—Sleeplessness in Fever—Case—Failure of different modes of Treatment—Use of Opiate Injections—Delirium Traumaticum—Constitutional Irritation from Blisters—Treatment—Sleeplessness in Hypochondriacs and Hysterical Females—On the use and abuse of Cold Applications to the Head.

GENTLEMEN,—Two cases which have been recently under treatment in this hospital, demand your particular attention,—the man who has been labouring under a severe attack of jaundice, and the boy who is recovering from fever. A remarkable symptom in both of these patients, and which must have repeatedly attracted your notice, was a total privation of sleep. In the former case the sleeplessness continued for a week, in the latter for nine or ten nights.

Sleeplessness is a very curious result of disease. It accompanies certain morbid conditions of the system brought on by actual disease, or by grief, care, and various other forms of mental disturbance, continues to harass the unhappy sufferer night after night, and frequently resists the most powerful and decided narcotics. I do not intend to enter into any inquiry respecting the different states of the constitution in which it occurs; my purpose is merely to offer a few practical remarks on the more obvious and striking examples, with the view of illustrating the cases to which I have directed your attention.

There is a form of sleeplessness which is frequently the precursor of insanity, and which

has been well described by my friend Dr. Adair Crawford. The watchfulness in such cases is accompanied by the well known symptoms of incipient mental derangement, and its treatment is therefore inseparably connected with that usually resorted to in cases of threatened insanity, and embraces the employment of means moral as well as physical. Of these it is not my intention to speak; I may observe, however, that Dr. Crawford has found opium, gradually increased to very large and frequently repeated doses so as to produce sleep, the best remedy.

In the case of jaundice, the patient passed several nights without any sleep. He was just beginning to recover from the jaundice when this new symptom appeared, and I directed your attention particularly to the circumstance, because every manifestation of nervous derangement connected with jaundice should be carefully watched. It frequently happens that jaundiced patients sleep too much, and in some cases the disease is accompanied by convulsions, succeeded by coma, most alarming symptoms, and almost invariably the harbinger of a fatal termination. Dr. Marsh was the first who directed our attention to the great fatality of those cases of jaundice in which convulsions occur; I have seen but one instance of recovery. It was in the case of a gentleman labouring under icterus, very considerable hepatitis, with enlargement of the liver and anasarca, with ascites. He was treated by Dr. Osborne and myself, and had at least a dozen long and violent convulsive paroxysms, ending in coma, succeeded by temporary forgetfulness and fatuity. Repeated leeching of the right hypochondrium, active purgation, and mercurialisation of the system removed all the symptoms of disease, and he slowly but perfectly recovered. A very able and original writer, Dr. Griffin of Limerick, has detailed the particulars of some interesting cases of this nature in the *Dublin Medical Journal*. You perceive, therefore, that in jaundice every thing denoting an unusual state of the nervous system, whether it be too much sleep or too little, demands your attention.

In this man's case the jaundice was the re-

sult of an attack of hepatitis. We treated it with leeches, blisters, and the use of mercury, and in the course of a few days the stools became copiously tinged with bile, and symptoms of improving health appeared. At this stage, the dejections being bilious, but the jaundice still remaining, he began to exhibit symptoms of restlessness and nervous irritability, and finally became perfectly sleepless. Here, gentlemen, we had to deal with a new symptom, extremely harassing to the patient, and likely to react unfavourably on the original disease. As a preliminary step I determined to evacuate the bowels, and for this purpose I prescribed a purgative draught, consisting of five ounces of infusion of senna, half an ounce of sulphate of magnesia, a drachm of tincture of senna, and a scruple of electuary of scammony. My object was to purge briskly, and then give a full narcotic. In all cases of jaundice depending on hepatic derangement, after you have succeeded in producing bilious evacuations, you should never omit prescribing an active aperient every second or third day for the space of ten days or a fortnight, with the view of carrying off the remains of the disease so as to prevent the occurrence of a relapse. Hence you will find such cases very much improved by the use of Cheltenham water, taken every day for three or four weeks *after the reappearance of a bilious tinge in the alvine discharges*. The stimulus of the purgative causes an increased flow of bile into the intestines, which removes the hepatic congestion, and carries off what is popularly termed the dregs of the disease, and promotes a rapid and complete recovery. It is a simple but successful practice, and I would advise you never to omit its employment in cases of this description.

With respect to purgative mixtures, I may observe that you should prescribe a larger quantity of the infusion of senna than is generally ordered, if you wish to secure its certain and decided operation on the intestines. Hospital nurses, who reason from facts and experience, know this, and when directed to give a senna draught they always give a small tea-spoonful. They administer from four to six ounces at a time, and I have observed that in this way the action of the medicine is more certain, and the benefit derived from it more extensive. I am convinced that the usual mode of giving this valuable purgative in private practice is bad; the quantity given is too small, and consequently it is necessary to repeat the dose several times, a mode of proceeding apt to occasion much nausea and griping, I would therefore recommend a quantity varying from three to six ounces, to be administered in all cases where the patient's condition will admit of free purging. A most accurate observer of the effects of medicines, Mr. Kirby, is in the habit of ordering purgative mixtures in chronic cases to be taken at bed time, and not, as is usually done, in the morning. He asserts that their action is

milder and less irritating to the bowels when the patient lies in bed and is asleep until the period of their operation, than if he were up and about.

After the purgative had produced four copious discharges, I prescribed eight minims of black drop, to be taken at a late hour in the evening. Whenever I give opiates to procure sleep, I always observe the rule laid down by Dr. McEride (a celebrated physician of this city), to select the period at which nature usually brings on sleep, and which varies according to circumstances and the habits of the patient. Whenever you have to deal with watchfulness in patients labouring under morbid states of the constitution, as, for instance, hectic, inquire when the tendency to sleep usually occurs, and administer your narcotic about an hour or two before its occurrence. It is between three and five o'clock in the morning that the inclination to sleep is strongest; it is about this time that sentinels are most apt to slumber at their post, and consequently attacks upon camps or cities, made with the intention of effecting a surprise, are usually undertaken about this period of the morning. How well marked is the periodic tendency to sleep at this hour in all patients labouring under hectic fever produced by whatever cause. How often do we hear the poor sufferer complain of restlessly tossing about in his bed until three or four o'clock in the morning, when at last sleep, welcome although uneasy, for a few hours separates the patient from his pains. If given at an early hour in the evening, the effect of the opiate is not coincident with this periodic attempt of the constitution, and it fails in producing sleep, but if exhibited at a late hour, it begins to produce its soporific effect at the very time when nature inclines the harassed sufferer to repose, and the result of these combined influences is a deep, tranquil, and refreshing sleep. By observing this simple rule, I have often succeeded in producing sleep in cases where various narcotics had not only failed, but even added considerably to the irritation and discomfort of the patient.

In cases of sleeplessness, where you have administered an opiate with effect, be careful to follow it up for some time, and do not rest satisfied with having given a momentary check to the current of morbid action. To arrest it completely, you must persevere in the same plan of treatment for a few days, until the tendency to sleep at a fixed hour becomes decidedly established. You must give an opiate the next night and the night after, and so on for five or six nights in succession, and where the watchfulness has been of an obstinate and persistent character, narcotics must be employed even for a longer period and in undiminished doses. I do not allude here to the sleeplessness which accompanies confirmed hectic and other incurable diseases; such cases require a particular mode

of treatment, and generally call for all the varied resources of medicine. But in those instances of watchfulness, which are frequently observed towards the termination of acute diseases, it is always necessary to repeat the opiate for some time after you have succeeded in giving a check to this symptom. You need not be afraid of giving successive opiates lest the patient should become accustomed to them, and a bad habit be generated, for the rapid convalescence and renewed health, which are wonderfully promoted by securing a sound and refreshing sleep, will soon enable him to dispense with the use of opiates.

Another disease in which sleeplessness is a prominent symptom, is delirium tremens. We have had an example recently in our wards, and you have seen the means employed to overcome it. The patient came into hospital with symptoms of extreme nervous excitement and watchfulness, which had continued for some time, and were brought on, as is most commonly the case, by repeated fits of intoxication, succeeded by a pause of perfect sobriety—in Irishmen the result of necessity or accident. In this man you must have remarked the signal benefit which attended the use of a combination of tartar emetic and opium, and how rapidly the watchfulness disappeared. I shall not enter into the details at present, as I purpose to return to this subject on a future occasion.

There is, however, one form of nervous irritability, frequently observed in persons who are in the habit of drinking freely, but without running into excess, and presenting as it were a shadow of delirium tremens, on which I shall make a few remarks. This curious state of the nervous system is generally found to exist in men about the middle period of life, and who consume a larger quantity of spirituous liquors than they are able to bear. Such persons, without suffering in appearance, or losing flesh, get into a chronic state of disturbed health, manifested by nausea, and even dry retching, in the morning, loss of appetite, and impaired digestion; but, in particular, by a deranged and irritable state of the nervous system, and by watchfulness. This forms one of the most distressing symptoms, and the patient generally complains that he cannot get any sound and refreshing sleep, that he lays awake for hours together, and that when he slumbers his rest is disturbed by disagreeable dreams, or broken by slight noises. How are you to treat this affection? I can give you a valuable remedy for this deranged state of constitution—one which I have often tried, and which, from experience, I can strongly recommend. It is a mixture composed of tincture of Columbo, quassia, gentian, and bark—say, an ounce of each; and to this is added a grain, or even two, of morphia. A compound tincture, somewhat analogous to this, is much in use among military gentlemen, and others, who have resided for a considerable time in the Indies, where, from the heat of the climate,

and the prevalence of intemperate habits, the stomach becomes relaxed and the nervous system irritable, so as to represent, in a minor degree, the symptoms which characterise delirium tremens. You perceive I combine several tonics to form this mixture, because they are well known to produce a more beneficial effect when combined than when administered singly; and I add to these a narcotic, which has the property of allaying nervous excitement without deranging the intestinal canal. The dose of this mixture is a teaspoonful three or four times a-day, and the best time for taking it is about an hour before meals. It gradually removes the nausea and debility of stomach, lessens nervous irritability and watchfulness, and, with a proper and well-regulated diet, and attention to the state of the bowels, I have seen it produce excellent effects. In such persons much benefit is derived from the use of the tepid shower-bath.

Fever is another disease in which sleeplessness is a symptom, frequently of an unmanageable character, and pregnant with danger to the patient. You witnessed this in the case of the boy who lies in the small Fever Ward, next to the man who is at present labouring under general arthritis. This boy had fever of a mild description, and unattended with any bad symptoms. His case scarcely required any attention, and he had almost arrived at a state of convalescence without the aid of medicine, when he began to lose his rest, and absolutely became sleepless for several nights. I beg your attention to this case, for many reasons. In the first place you have seen that we tried many remedies without success, and afterwards fortunately hit on one which answered our purpose completely. Let us examine the nature of the medicines prescribed, and our reasons for giving them.

In the first place, we gave, as in the case of jaundice, an aperient, followed by a full dose of black drop. It failed in producing any sleep; we repeated it a second and a third time, but without the slightest benefit. I then remarked to the class, that as I had noticed the good effects resulting from a combination of tartar emetic and opium in the case of delirium tremens, where opium alone failed in procuring sleep, it would be proper to give this remedy a trial. I observed at the same time, that I was convinced that the preparations of antimony have a distinct narcotic effect, and that I had seen patients in fever whose watchfulness had been removed by antimony given in the form of tartar emetic or James's powder. I said it was my firm impression that tartar emetic, along with its other effects, exerts a decided narcotic influence on the system, and that it is this which makes it so valuable a remedy in treating the sleeplessness of fever and delirium tremens. Hence I have been in the habit of giving tartar emetic combined with opium in fever, and, I must add, with very great success. Our predecessors were much in the habit of using antimonial

mixtures in the treatment of fever, and they did this because they knew, by experience, that these remedies worked well. It is at present too much the fashion to decry their practice, and in this instance I think with very little justice.

In this boy's case, however, the combination of tartar emetic and opium did not succeed in producing sleep. Having thus failed in our first and second attempts, we had recourse to the liquor muriatis morphiæ, a preparation first brought into use by Dr. Christison, and which, in the form usually employed, is equal in strength to laudanum. It is an exceedingly valuable preparation for many reasons, and one which has the strongest claims to your notice. Being of the same strength as laudanum, it saves the trouble of learning and remembering new doses, and, in addition to this, it possesses the more important advantages of inducing sleep with more certainty, and not acting as an astringent on the bowels, or affecting the head so frequently as laudanum. You observe that I say so frequently; I do so because cases now and then occur in which even moderate doses of the liquor of the muriate of morphia produce quite as much head-ach as laudanum. I prescribed the former in doses of fifteen drops every six hours, so as to give sixty drops in the day, and continued this practice for two days, but without the slightest effect. Here you see three modes of inducing sleep completely failed. The boy remained for a day without taking any medicine, and then we made another attempt, which was more successful. We first prescribed a purgative enema, and, after this had operated, he was ordered an opiate injection, consisting of four ounces of mucilage of starch, and half a drachm of laudanum. He fell asleep shortly after using the opiate injection, and did not awake until the next morning. The following night the opiate was repeated in the same form and with equal success; convalescence went on rapidly, and the boy's health is now quite re-established.

Here, then, is a singular fact, attested by this case, that opiates in the form of injection will succeed in producing sleep, where they have completely failed when administered even in large and repeated doses by the mouth. Baron Dupuytren was the first who made this important observation, and proved that narcotics applied to the mucous surface of the rectum exercise a powerful influence on the nervous system, always equal, and very often superior, to the effect produced by taking them into the stomach. He maintains, that in delirium traumaticum and delirium tremens a certain quantity of opium, when prescribed in the form of enema, will act with more decided effect in allaying nervous excitement, than the same or even a larger quantity when taken by the mouth. I have no hesitation in giving full credit to this assertion, as the results of my experience tend strongly to confirm its truth. I have, not long

since, published, in the *Dublin Med. Journal*, the case of a patient in Sir P. Dun's Hospital, who was reduced to the last stage of debility and emaciation from the combined effects of mercury and syphilis. The torture which this man endured from nocturnal pains and a total deprivation of sleep, was such that he swallowed enormous doses of opium; in fact, he had, previously to his admission into Sir P. Dun's Hospital, exhausted all his means in purchasing opium. While in hospital he used to take 150 drops of black drop in the course of a day, and yet, notwithstanding these excessive doses, he could only get a few minutes of unrefreshing slumber. After some time I changed the plan of treatment, and had the black drop administered in the form of enema. It succeeded in producing a decided soporific effect, and in a short time he was able to enjoy a sufficient quantity of repose, from taking only one-tenth of the quantity used by the mouth. I have also, in the same paper, adverted to the case of a medical gentleman who laboured under an affection of his joints, which was accompanied by spasms of the limbs and most excruciating pains. His agony was so intense that he used to swallow grain after grain of opium, until he had taken to the amount of 30 or 40 grains, with the view of procuring some alleviation of his sufferings. He was prevailed on to give up altogether the use of opium by the mouth, and employ it in the form of enema, which he did with the most striking advantage, the quantity which succeeded in giving relief in this way being scarcely the twentieth part of what he ordinarily used.

It is unnecessary for me to enter here into any discussion with respect to the nature and treatment of delirium traumaticum, and the sleeplessness which always accompanies it, as you will find this subject very ably treated in M. Dupuytren's works, and in a very instructive and elegant lecture delivered by Mr. Crampton (the Surgeon General) in this hospital, and published in the last volume of the *London Medical and Surgical Journal*. There is, however, one kind of sleeplessness arising from irritation of the skin produced by blisters, which frequently assumes a very serious character, and on which it may be necessary to offer a few observations, as the subject has not been noticed sufficiently by practical writers. Trifling as the irritation resulting from a blister may seem, yet, under certain circumstances, it is a symptom of highly dangerous aspect, and becomes a source of just alarm. I have witnessed the loss of some lives from this cause, and many patients have, to my knowledge, been rescued from impending danger, by an early and proper share of attention being directed to its phenomena and treatment.

The bad effects on the nervous system occasionally produced by the application of blisters, are somewhat analogous to those which result from wounds and other external injuries, and to be accounted for on the same principle.

Wounds and injuries sometimes make an impression on the nervous system, by no means proportioned to the importance of the injured organ to life, or to the extent of the mischief. An injury produced by a body which strikes the sentient extremities of the nerves with great force, will sometimes produce very remarkable effects on the system. Thus a musket ball striking a limb may, without wounding any great artery or nerve, or destroying any part of importance to life, produce a train of nervous symptoms of an extraordinary character. The person, without feeling much pain, and scarcely knowing that he has been wounded, without being terrified, or having his imagination excited by any apprehended dangers, turns pale, gets a tendency to faint, and sometimes actually dies from the impression made on the nervous system. In the same way, an external injury reacting on the nerves may bring on high mental excitement, delirium, and a total privation of sleep, as we exemplified in delirium traumaticum. I mention this with the view of establishing the proposition that impressions made on the sentient extremities of the nerves are sometimes reflected on the nervous centres, producing the most alarming effects. In this way we can understand how the irritation of blisters may produce sleeplessness, mental aberration, and a train of symptoms analogous to those which characterise delirium traumaticum.

The delirium and sleeplessness arising from the irritation of blisters is by no means an uncommon disease. I have seen many examples of it in private practice, and I am anxious that you should be acquainted with its nature and treatment. It is generally met with in the case of children, in whom the cutaneous surface is extremely tender and irritable. I could relate several instances in which I have been called on to visit children labouring under fever, where symptoms of high nervous excitement were present, and where I found the little patients delirious, screaming, and perfectly sleepless from this cause. I have found this alarming affection generally occurring at an advanced stage of fever, and exhibiting a train of symptoms which closely resemble hydrocephalus. I have observed that after the application of a blister to relieve some suspected cerebral, or abdominal, or thoracic affection, jactitation, restlessness, constant application of the hand to the head, and delirium have appeared, and that these symptoms had been mistaken for incipient cerebritis or hydrocephalus, and treated with leeches and purgatives. When the blister had been applied to the nape of the neck, the soreness and irritation of the skin on that part *cause the child to roll its head from side to side on the pillow, with that peculiar motion and scream supposed to prove to a demonstration the existence of hydrocephalus.* I have learned also, that the above measures, so far from giving relief, have only tended to produce an exacerbation of the disease, and that the medical

attendant has given up the case in despair. Now, gentlemen, if called to such a case what should be your practice? In four cases of this kind I gave my opinion frankly to the medical attendant, and told him he was pursuing a wrong course, that the disease was analogous to delirium traumaticum, and not to be treated by leeches or purgatives, and least of all by blisters. I observed to him that these symptoms had made their appearance shortly after the child had been blistered for suspected disease of the belly, or head, or chest; and that it was useless to attempt to remove the disease by leeches, or purgatives, or blisters. The remedy I always proposed was opium, and it was acknowledged in four or five cases, that this remedy had succeeded not merely in relieving the existing symptoms, but in saving the patient's life. In such cases, particularly in young children, the opium must be given in small but frequently repeated doses, so as to ensure its energetic, but safe action, and the greatest care must be taken to soothe the irritated portion of the skin, by ointments, poultices, &c., *while unwearied diligence must be bestowed upon the task of preventing the child from scratching the blistered surface.* To effect this the child's hands must be muffled in appropriate gloves, and must be secured in the sleeves of a shirt made for the purpose.

I beg your attention still further to this subject of sleeplessness and delirium. I wish to mention the case of a gentleman who was a pupil of mine. This gentleman studied hard, attended lectures regularly, and was constantly in the dissecting room. While thus occupied, he happened to wound one of his toes in paring a corn, and afterwards wore a tight shoe on the injured foot. A small imperfect abscess formed in the situation of the corn, which was opened by one of his fellow students; the incision gave very great pain, and was not followed by any discharge of matter. Next day he was feverish, and the lymphatics of the injured limb became extensively engaged, the inflammation ascending towards the glands of the groin, and having a tendency to form a chain of insulated patches in different parts of the leg and thigh along the course of the lymphatics. This you will generally find to be the case in inflammatory affections of the lymphatics; the inflammation is seldom continuous, but, in the majority of cases, is developed at certain insulated points, where small diffuse suppurations form very rapidly. After a few days, this young gentleman's fever increased to an alarming height, he became completely sleepless, and had incessant delirium. He was purged briskly, leeches extensively and repeatedly, his head shaved, and cold applications so constantly applied, that he appeared half drowned and collapsed. Notwithstanding this very active treatment, not the slightest relief was obtained; neither were the symptoms mitigated by incisions made in the inflamed patches for the purpose of evacuating matter; the sleeplessness continued,

and the delirium was as wild as ever. I saw him on the seventh or eighth day, when all antiphlogistic measures had failed, and his friends were quite in despair. On being asked my opinion, I stated that I looked upon the case as one of delirium, not proceeding from any determination to the head or inflammation of the brain, but depending on a cause analogous to those which produce delirium traumaticum, and that instead of antiphlogistics I would recommend a large dose of opium and some porter to be immediately given. Mr. Cusack who visited the patient after me, concurred in this view, and a full opiate was administered in repeated doses. It succeeded in producing sleep and tranquillising the nervous excitement. I may here observe that a few days afterwards this gentleman had a return of the symptoms of cerebral disturbance with sleeplessness, in consequence of omitting his opiate, and that the opiate and porter were again administered, and again succeeded in removing the delirium and watchfulness. By perseverance in the use of the same means, the disease was completely removed, and convalescence established.

The last kind of sleeplessness to which I shall direct your attention, is that which is frequently met with in persons of a nervous and irritable disposition, in hypochondriacs, and hysterical females. You will find such persons, although of active habits, and with tolerable appetites, complaining of a total privation of their natural rest, and it is astonishing to think how long they may continue subject to this harassing watchfulness. I have frequently observed this affection among females of nervous habit, who possessed strong feelings of attachment to the interest and welfare of their families, and who were remarkable for an exemplary and over anxious discharge of their domestic duties. It is also very often met with in the upper classes of life, where the susceptibility to nervous excitement is morbidly increased by fashionable habits. I shall not enter into the various moral causes which tend to produce this state of the nervous system, and will content myself for the present with giving you some hints for the treatment of this obscure affection. As yet I have not any distinct and accurate notions of the disease, and can only guess at the treatment, but this much I may state, that such cases are not to be cured by the means which I have already detailed. If they are to be cured by any means, I think it is by antispasmodics, and remedies which have a gently stimulant, and, if I may so express myself, alterative effect on the nervous system. I have cured two cases of this kind by musk and assafoetida, where every other remedy had failed. To one of these I was called by my friend, Dr. Neason Adams; the patient was a lady of delicate constitution and hysterical habit; she was emaciated, and suffered from a total loss of rest, but had no other disease. All kinds of narcotics had been tried unsuccessful-

fully, and opium in all its forms had failed in procuring sleep. I advised the use of musk in doses of a grain every second hour, and this means proved eminently successful. In another case I succeeded by administering the same remedy in combination with assafoetida. I have also remarked that assafoetida alone, given in doses of two or three grains three times a-day, has very considerable effect in calming nervous irritation of this description, and restoring the patient to the enjoyment of more prolonged and refreshing sleep. In all such cases the physician must be most careful to have the appearance of not thinking the loss of sleep as a matter of much consequence, and the family of the patient must be directed to speak as little about the matter in his presence as possible;—nay, so powerful is the operation of moral impressions, that in one case which I attended along with Mr. Halahan, I succeeded in procuring sleep by ordering a musk pill to be given every second hour night and day, and by desiring the patient to be awakened, should she be asleep, at the time the pill was to be taken. I laid great stress on the importance of so proceeding, and thereby produced so strong an effect on the patient's mind, and inspired so great a confidence in the efficacy of the medicine, that she went to bed, not so much afraid of lying awake as afraid of being asleep at the hours when she ought to take a pill. The idea which had hitherto fixedly occupied her mind was displaced by a new impression and relief was obtained the very first night.

In affections of the head occurring in acute diseases, and attended with raving and loss of rest, it is a very usual practice to direct the application of cold lotions to the shaved scalp.

Permit me, gentlemen, to make a few remarks upon this important subject. I wish I could make myself well understood on this point, for I have seldom met with any person who seemed to bear in mind the true principle upon which cold is applied as a means of repressing local heat. In cases of determination of blood to the head occurring in fever, the common practice is to have the head shaved and cold lotions applied. Enter the room of a patient who is using cold applications, and you will observe the process conducted with great apparent nicety; the head is accurately shaved and carefully covered with folds of linen wet with a lotion to which spirit of rosemary or some odoriferous tincture has communicated an agreeable and refreshing smell; but when you come to examine the patient, you find his head smoking and the heat of his scalp increased. The nurse applies the lotion once every half hour, or perhaps not so often; indeed, she seldom repeats the application until her notice is attracted by the steam rising from the patient's head, or until she herself, awaking from a comfortable sleep, and going over to examine the state of the patient's head, finds the folds of linen which cover it as hot and dry as if they had been hung

before a fire. Whether applied to reduce local inflammation in any part of the body, or to cool the scalp in determination to the head, cold lotions as ordinarily employed do infinitely more harm than good. The cold is applied at distant intervals, its effect soon ceases, and reaction constantly takes place, leaving the part as hot or even hotter than it was before.

If you put your hand into snow for a few moments, and then take it out, it quickly resumes its natural heat; and if you repeat this at considerable intervals, so as to give time for reaction to occur, the vessels assume a more energetic action, and it becomes hot and burning. If you continue to keep it in the snow for a long time, its heat becomes completely exhausted, reaction does not take place until after a considerable period, and very slowly, and the hand remains at a very low temperature for a good while. Bear this in mind, for it will direct you in the application of cold to reduce local heat. If cold applications be used at such intervals as to allow the scalp to react and resume its heat, rely upon it, it is much better to forbid them altogether. Where you wish to apply cold with effect, let it be done by relays of folded linen, wet with any frigorific mixture, and repeatedly applied to the scalp so as to leave no smoking, or, what is much better, get three or four bladders, put into each a quantity of pounded ice, and apply one over the crown of the head, one on each side, and lay one on the pillow for the back of the head to rest on.

There is a vast difference between a thing being done and its being well done, so it is with regard to cold lotions; so difficult is it to ensure their proper application, that I have entirely given them up in hospital practice, and rarely order them in private. I have been induced to abandon them in consequence of witnessing so many instances in which my directions were neglected, and consequently the cerebral congestion was augmented by their mal-application. Another serious inconvenience frequently arises from their use when applied in a slovenly manner, which is the danger of cold arising from the pillow and bed-clothes being wetted.

It is a curious fact that the head is the only one of the three cavities with respect to which long established custom has laid down the maxim, that when its contents are inflamed we may cool the surface over it, while, in inflammatory affections of the thoracic or abdominal viscera, this practice is avoided as dangerous and inapplicable. Latterly, however, some medical men have been inclined to question the grounds on which cold applications have been rejected in the two latter cases, and some have even declared that they have used ice poultices in inflammations of the chest and belly with great success and perfect safety. I am not as yet prepared to adopt this practice, although I must confess that a review of the subject might incline me to give up my pre-

judices on this point. It is certainly but reasonable to think that what is true of the one may be also true of the other, and that the application of cold to the head and heat to the chest and belly has nothing in its favour beyond mere custom. It should be recollected, however, that the head and face are more accustomed to cold than the chest and belly, and hence are less liable to any mischief likely to arise from its application in an intense degree. Still I am inclined to think that there is much prejudice connected with the practice of applying cold to the head; and I have very little doubt that if the matter was properly investigated, and a number of experiments made, it would lead to the abandonment of cold applications in most inflammatory diseases of the brain. In fevers, I can say positively that in the majority of cases they are positively injurious, *as usually applied*; sponging the bare scalp with tepid or warm vinegar and water, or *even frequently repeated steeping of the head and temples* will often succeed much better in abating the head-ach and restlessness of fever than any cold applications whatsoever. In 1832, a violent influenza, accompanied by most distressing head-ach, attacked thousands in Dublin; this intense pain in the head was relieved by nothing so effectually as by diligent steeping of the temples, forehead, occiput, and nape of the neck *with water as hot as could be borne*.

I do not speak here of the application of cold to the head, for the purpose of relieving local heat and inflammation, but to produce an effect on the whole system. Cold thus applied is of decided and unequivocal value. You are aware that in cases of fever accompanied by symptoms of high mental excitement and great heat of skin, the use of cold dashing has produced the most extraordinary effects. Again, if a patient has taken too large a dose of prussic acid or any other narcotic, the best mode of rousing him is by pouring water on his face or chest from a height. In Turkey, if a person happens to fall asleep in the neighbourhood of a poppy field, and the wind blows over it towards him, he becomes gradually narcotised, and would die, if the country people who are well acquainted with this circumstance did not bring him to the next well or stream, and empty pitcher after pitcher on his face and body. This occurred to my friend, Dr. Oppenheim, during his residence in Turkey, and he owes his life to this simple but effectual treatment.

To conclude, gentlemen, I may observe that sleeplessness in a chronic form is often produced by dyspepsia, and can only be relieved by the means suited to indigestion. Here it is that small doses of blue pill and tonic purgatives are of infinite service, combined with change of air, of scene, and an appropriate diet. In many females, sleeplessness is combined with menstrual irregularity, and can only be cured by means calculated to invigorate the health and restore the catamenial

discharge to its natural periods and quantity, for the nervous system suffers equally whether they be suppressed or overabundant. It is singular how long sleeplessness often continues in chlorosis without inducing those serious consequences that are produced by this symptom in other morbid states of the system. In such cases much is sometimes accomplished by means of the common preparations of morphia, or by the use of Hoffman's liquor (liquor æthereus oleosus), camphor, and other medicines that act upon the nervous system. It must be confessed, however, that these and every other expedient to obtain sleep often fail in chlorotic and hysterical females, in whom relief is only obtained by a gradual improvement of the general health and menstrual function.

LECTURES

ON

*MIDWIFERY & THE DISEASES
OF WOMEN AND CHILDREN,*

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

—

LECTURE XXIII.

Treatment after Labour—Lactation.

GENTLEMEN,—In my last lecture I endeavoured to impress upon you the great importance not only of ascertaining whether the uterus has contracted, but also whether it *remains* so after labour. I instanced to you the melancholy fate of a Crown Princess of Austria from this cause; and there is every reason to know that a Crown Princess (if we might so call her) of this kingdom was lost in a similar manner, and under remarkably similar circumstances. The sad event to which I allude is so recent as to be almost within the recollection of some of you. Before proceeding further, I find that there are some observations on the management of the placenta which I omitted in my last lecture, and which require notice.

When the placenta is detached it presents itself to the os externum, with its smooth surface outwards: it is, in fact, inverted. Mauriceau, La Motte, Stein, sen., and others, were all in the habit of delivering the placenta immediately after the birth of the child. This method cannot be too strongly deprecated, for besides putting the patient to unnecessary pain, by introducing the hand into the uterus, we run the risk of injuring this organ by prematurely tearing off the placenta, and thereby inducing inflammation and organic disease, besides incurring, at the moment, no slight danger of hæmorrhage.

After the separation of the child from the mother, the accoucheur should take the cord in his left hand, and pass the fore-finger of

his right hand along it into the vagina. If he feel the spongy mass of the placenta within reach, he may pull gently with his left hand, pressing the cord towards the hollow of the sacrum with the fore-finger of his right hand, which will then act as a pulley, and enable him to pull the placenta in the axis of the superior aperture of the pelvis. If it follows, well and good, but if it resists, he must not continue to pull, but wait patiently for the accession of fresh pains, which seldom fail to detach it. When the placenta presents itself at the external opening, instead of continuing to extract it by the cord, we should grasp it with the thumb and four fingers, and turn it round three or four times as it comes out; by this means the membranes are twisted into a cord and come away entire. If this be neglected, and the placenta brought away at once, the membranes are apt to be torn and pieces of them left behind, which, by all means, should be avoided, for they not only produce a highly fetid discharge, and frequently a considerable degree of fever; but, when expelled, they create much alarm in the patient's mind, and frequently bring the practitioner into disgrace with the family.

After labour, the nurse must wash the external parts with a sponge and warm water, in doing which she should be careful never to wipe from the pubes backwards, for if there be the slightest laceration in the perinæum, as is almost always the case in primiparæ, it causes considerable pain; hence, in cleaning her patient, she must always carry her sponge or napkin from behind forwards.

In twin cases, when the first child is born, and, upon placing our hand upon the abdomen of the mother, we perceive that there is still another child in the uterus, it is commonly directed that we should make two ligatures upon the cord;—as I before said, I believe this to be a useless precaution. Twin births are decidedly more dangerous than single ones; the uterus is more distended; the part where the placenta is attached is of greater extent; hence there is greater danger of hæmorrhage, &c. Generally speaking, the placenta of twins form one mass, which is the contrary of what is usually taught in the works on midwifery, although, at the same time, they have no connexion with each other. We cannot be too cautious how we extract the placenta of twins. Although the cord will often seem to follow when we pull it, still we must not do so, for prolapsus or inversion of the uterus may be the result. We must twist the two cords together, as thus we shall pull them equally, and avoid the chance of rupturing either. The placenta, also, are more equally detached, and come away better. When they approach the os externum, the same rule must be followed as where there is but one placenta; they must be grasped by the whole hand, and rotated four or five times to ensure the membranes coming away whole. Where the abdomen has been much distended, it is recommended

to bind a broad band round the patient. In twin cases, this should be done after the birth of the first child, and gradually tightened as it diminishes in size, in order to give support to the uterus and abdominal parietes.

I will now call your attention to a few other points, which, although not perhaps of such absolute necessity as the directions which I have just given respecting the management of labour, are nevertheless highly important, and should be held in mind by every practitioner who enters the lying-in room of a patient. The directions for the conduct of an accoucheur towards his patient at the time of labour, which Dr. Dewees has given, are so excellent that I shall quote some of them; the rest, as well as the whole chapter on this subject, I recommend to your attentive perusal.

“1st. Let all communications to the patient of a delicate nature be conducted by a third person; the nurse, when present, should be that person—in her absence, any elderly friend.

“2nd. Endeavour, by a well-chosen conversation, to divert the patient's mind as much as possible from the purpose of your visit, when your services are not immediately required.

“3rd. When your presence is not absolutely necessary in the sick room, be as little in it as will be consistent with your duty to your patient; by this you may remove restraint, and apparently abridge the period of your watching.

“4th. Should the situation of your patient, in your opinion, require to be ascertained, let the proposition be made by a third person—as the nurse, and urge, in defence of the request, all the circumstances which led you to believe it would be important, as the length of time she had been in labour, the force and frequency of her pains, the evacuation of the waters (if it had taken place), and, above all, to ascertain the progress of the labour, and whether the presentation be a proper one.

“5th. If, after you have made your examination, you should be importuned for your opinion of the nature of the presentation, and the duration of the labour, do not commit yourself by any positive declaration, unless you are certain of the first, and pretty sure as to the latter.

“6th. Before you proceed to the examination, let your patient be placed with the most scrupulous regard to delicacy, as the slightest exposure is never necessary.”

Lactation.

As soon after labour as can conveniently be done, the patient's wet linen should be removed, as far as is possible without disturbing her too much, and clean well-aired clothes substituted. She should be left to the most perfect quiet both of body and mind, in order that if possible she may have some sleep; for, as Carus well observes, the refreshment of sleep seems to be the most powerful and natu-

ral means of inducing full contraction of the uterus. When these arrangements have been made, and the patient has enjoyed two, three, or more hours' sleep, it is important that the child should be applied to the breast as soon as possible. Its mother's breast is the most natural position for a new-born child, for at this tender age it is not capable of supporting its own heat. Thus we see in many animals, that for a certain period after birth the young ones shelter themselves beneath their mother to preserve a degree of warmth, which of themselves they could not produce at this early age. “Every mother who has been strong enough to carry and nourish her child during the nine months of pregnancy, is also strong enough to afford it the breast for some time after birth*.” The child can suck the moment it is born, for the power of instinct is quite as strong in this case as in the brute. If healthy and vigorous it immediately seeks for its mother's breast, and, if it does not find it, it sucks at every thing which touches its mouth, even its own little hand, or the finger when presented to it.

Before speaking of the management of the breasts, it will be necessary to give you a short description of this organ. The breast consists of a large conglomerate circumscribed gland, mixed with a considerable quantity of fat; the glandular substance is composed of a congeries of small convoluted arteries, veins, and nerves; the ultimate arteries, before they terminate in their correspondent veins, detach minute branches for the separation of the milk, which, uniting as they proceed to the nipple, form small canals called *lactiferous tubes*, these are about seven or eight in number, communicating with the basis of the nipple, and generally opening at its apex by the same number of ducts, though sometimes two of them open by a common orifice. The ducts adhere to a strong ligamentary elastic substance, which is continued from the gland and terminates with the ducts in the nipple; this ligamentary substance, and these ducts which it contains, are capable of extension and contraction to a great degree, and in their natural state are moderately folded, curled, or corrugated, by which mechanism the place of valves is supplied, and the involuntary eruption of milk prevented, unless the distending force be very great, from the accumulation of too great a quantity. The whole substance of the nipple is spongy, elastic, and subject to different changes, becoming sometimes hard, sometimes flaccid, sometimes flat and sunk into the breasts, and sometimes prominent; its outward surface is prominent and full of small tubercles; the nipple is surrounded with a disk, or circle, of a different colour, called *areola*, and on the inside of the skin of the areola are disseminated little glands, known to anatomists by the name of sebaceous glands; these supply an oily mucus to defend

* Boer.

the areola from abrasion, which would otherwise be the consequence of suction, and likewise to glue up the mouths of the lactiferous tubes; the skin upon these parts is extremely thin, and consequently the nervous papillæ lie very bare, and are very liable to irritation*. The breasts usually contain more or less milk before the patient is delivered, or at least soon after her labour, this is called *colostrum*; if the child be applied in three or four hours after, or, in fact, as soon as circumstances will permit, it draws this gradually out, and, by the repeated and agreeable excitation of sucking, induces a gentle secretion and evacuation of milk from the breast, so that it is never too empty or too much distended; hence the mother is spared the pain and accompanying milk fever, which would otherwise occur. The advantages of this early application of the child to the breast (says Dr. Dewees) are 1st. the child retains the early faculty of sucking with which it is born, for if this be not attended to for several days, because (as they say) the mother has no milk, it will lose it, and much trouble be given to recal it. I have witnessed this but too frequently. 2dly. It will, by its gentle action upon the nipple, gradually stretch it, and accustom it to this extension before the breasts become swelled with milk, and tender from distension. 3dly. By its mouth stimulating the nipple an earlier secretion of milk will take place. 4thly. The milk will be drawn off as fast as formed, which will prevent the pain which constantly arises from its accumulation, as well as the swelling which is almost sure to follow its formation; this swelling shortens the nipple, and renders the extraction of the milk more difficult, this increases the efforts of the child, by which the external covering of this important little body becomes irritated, and sore nipples now ensue to the great misery of the mother. 5thly. The early secreted milk has a purgative quality attached to it, by which the infant profits, by its assisting to carry off the meconium. This milk fever, which people think so necessary for obtaining a supply from the breast, is merely the result of their own neglect; if the child be not applied no fulness of the breasts is perceivable, and a small quantity of watery fluid only comes out; at length, if the breast be not drawn, it swells, the face flushes, the skin becomes hot, and all the common symptoms of milk fever are induced. "It is not to be wondered at," says Mr. C. White, "that a secretion, which has been so many months in preparing, and which is intended to flow in such large quantities for so many months to come, should, if driven back, in a few days occasion a fever, especially when we consider that the milk, which is secreted in the breast for several days after delivery, is, when in its purest state, thin, stimulating, and purgative, for the wise purpose of cleansing the child's stomach and bowels of those viscid blackish

green fæces, called *meconium*, and that this milk must be rendered very acrid by its stagnation in the breasts for several days together." "I have observed, says Dr. Hunter, "in women, who do not give suck, and in nurses, after they leave off suckling, that the axillary glands become painful, swell, and sometimes suppurate; is not this owing to the acrimony which the milk has acquired by long stagnation in the breast, and affecting the gland through which it must pass in absorption? I have observed, too, that they are at the same time liable to little fevers of the intermitting kind, but very irregular in their return, which come on with a rigor and go off with a sweat, are not such fevers raised by absorption of acrid milk?"

As often as the child feels thirsty, or in other words hungry, it betrays evident signs of wanting the mother's breast, this one can instantly perceive, if the child be lying by its mother's side, and enjoying the warmth of her body; in fact, the maternal warmth is as necessary to its well doing, as the wing of the hen to the newly hatched chicken; children suck best when lightly but sufficiently warmly clad, have their feet and hands free, and can lie by their mother's side. Whatever renders the nipples soft and tender renders the operation of sucking difficult, because the child can draw them out too easily; we should rather endeavour to have them firm and less sensitive of irritation, just as they would be if they had not been always covered by the dress from the earliest childhood, and thus rendered perfectly unfit to perform the office designed them by nature. The best means of obtaining this object is by means of exposing them frequently to the air during the latter months of pregnancy, and by dabbing them occasionally with cold water, mixed with a little lavender water, or eau de Cologne. If the patient do not suckle her first child, nor have her breasts drawn, she will seldom have much milk secreted in her subsequent lyings-in, and what is secreted will easily be absorbed.

In a few hours, therefore, after delivery, as soon as she has had a little rest, she should sit up in bed, with a bed-gown thrown over her shoulders; if she proposes to suckle her child it should now be laid to her breast, *whether there be signs of milk or not*; this should be repeated every four or five times a-day, but at night it is not necessary either that the breast should be administered, or that any kind of food should be given to the infant. After the first six or eight weeks, when the child ceases to be indifferent to the surrounding objects, and now begins to notice and express its pleasure by smiling, the mother should suckle it at certain hours, and accustom it to go without during the intervals; for instance, it should only be applied every three or four hours; the intervals of suckling should not be guided by the convenience of the mother, but by the wants of the child. The patient should lie very high with her head and shoulders, and

* C. White on Lying-in Women.

should sit up in bed when she takes her food, and as often as she suckles her child, and should kneel whenever she has occasion to pass water, which should be done frequently; this frequent upright posture is of the utmost consequence, and cannot be too much enforced, it prevents the lochia from stagnating, the stools and urine from being too long retained, and promotes the contraction of the uterus, together with that of the abdominal muscles; the patient, moreover, should keep her breasts and shoulders well covered, in order to promote the secretion of milk.

Nothing can be a more mistaken notion that it is always necessary to add rich and stimulating food to the diet of a woman who is suckling; the stomach thus soon becomes overloaded and deranged, and so far from producing an increase in the secretion of milk, the reverse is the case, and diminution is the result; this is not infrequently observed among wet nurses. A healthy young woman, accustomed to a country air and life, is induced to take a wet nurse's place in town. She is now confined in a great measure to the house, takes little exercise, keeps later hours, eats, *ad libitum*, of better and richer food than she has been accustomed to, and, in order to keep up her milk, is allowed a certain quantity of porter daily. With all this, her milk, to the surprise of her mistress, diminishes in quantity, and, under the supposition that more support is still required, a glass of wine is perhaps recommended, in addition to what she had before. The result of all this is, that the bowels become deranged; she suffers from severe throbbing headach, the face is flushed, the skin hot, and the pulse full and hard; under these circumstances, the very means which have been used to increase her milk, have had the effect of diminishing its secretion. Purgatives, strict antiphlogistic regimen, and, in some cases, even venesection, must be had recourse to, before we shall succeed in restoring the milk to its former quantity. In saying this, gentlemen, I do not pretend to deny that a moderate increase of food, more especially mild unirritating fluids, have a considerable effect in increasing the quantity of milk, the patient, moreover, requires this addition to support the drain upon her system which has now commenced.

One of the chief causes of misery among new born children, is a want of that degree of cleanliness so necessary to health. In washing the child immediately after birth, it is sometimes very difficult, or even impossible, to remove the smegma or vernix caseosa by mere soap and water; a little pork lard, or cold cream, is generally used in such cases, but this only makes the child greasy, which is not desirable. In the district of the Lower Rhine, and in France, they heat a little white wine in a cup with a piece of fresh unsalted butter, and rub the child with this liniment, which effectually removes any vernix caseosa which may adhere to the skin. This is a practice of some anti-

quity in France, for Portal mentions a case where it was used as early as 1667, and Dionis, who published in 1718, mentions it also. The child cannot be kept too clean. It is impossible to expect that a hired nurse can take so much care of a child as its own mother, and this is one of the many reasons why children of rank do not thrive so well as those of the middling classes who are nursed by their own mothers. The nursery cannot be kept too clean, or the air too pure; the room should be spacious, and, above all, have plenty of light, for this great agent of life is quite as necessary for a child as for a plant. Under the care of a nurse, also, the person of a child is never so clean as when its mother takes charge of it herself. From neglect of this sort we frequently see the skin at the groins, between the thighs and nates, behind the ears, &c., become excoriated, and the poor little thing is kept in a continued state of irritation and uncomfortableness; no wonder that its health soon suffers.

It is frequently a question how long a child ought to be suckled. The teeth begin to distend the gums towards the seventh month; this is known by the increased secretion of saliva, and by the child putting every thing into its mouth which it can lay hold of. This is pure instinct. It will now take a piece of soft bread more eagerly than the breast, nor does it seem to care so much for a diet which is entirely fluid. In the ninth or tenth month it becomes still less inclined to suck, and the milk generally begins to decrease in quantity.

So much, gentlemen, for the observations on lactation which I think it necessary to make at present; at a future part of the course, when I come to speak of diseases of children, especially during the first month, I shall then enter more fully into this subject.

After labour, most women, except primiparæ, are liable to spasmodic pains about the uterus, varying considerably both in severity as well as in the frequency of their occurrence. These are called *after-pains*, and are considered to arise from the presence of coagula in the uterus, which irritate and excite it to contract and expel them. During one of these attacks of pain the uterus is harder than at other times, and even tender to the touch, and we must be very careful to distinguish them from the pain of inflammation, which they frequently resemble considerably, and even occasionally pass into. Although the abdomen is tender on slight but sudden pressure, yet, if *gradually* applied, you will find it capable of bearing a considerable degree of pressure, not only without increasing the pain, but even with the effect of lessening what she is already suffering from.

It is generally supposed, as I have already mentioned, that these after-pains are produced by the presence of coagula lodging in the uterus, and to a certain extent this is the case; but we not infrequently see the severest after-pains where the uterus must be tolerably

free from coagula, and it is to Dr. Burton, of York, that we are indebted for some very curious observations upon this subject, by which, in my opinion, one of the causes at least is satisfactorily explained. "Upon the expulsion of the child and placenta, the orifices of the uterine sinuses must contract, and thus retain the grumous blood which is in them; hence the use and benefit of these after-pains, which, by stimulating or compressing the vessels and muscular fibres, make them exert their force to squeeze out this grumous blood, which otherwise might remain there and occasion inflammations, suppurations, &c., from all which we find that these after-pains are necessary towards removing or preventing an inflammation of the womb; therefore we must not be too forward in giving strong opiates and other internal medicines which may take them off, while this grumous blood is lodged within those sinuses. I doubt not but those patients who die from the eighth to the fourteenth day, whose uterus has been inflamed with the symptoms above mentioned, have been injured by the too free use of opiates." Dr. Burton mentions a case to which he was called about an hour after delivery on account of very severe after-pains. Having introduced his hand with some difficulty, he found a piece of placenta still adhering to the fundus; this he gently removed; "in doing this," says he, "I perceived several small membranous strings, as I then thought them, adhering to the uterus; but I was soon undeceived, for upon expanding my fingers, by which I stretched the womb a little, several of these came into my hand, which I drew out, and found what I had imagined to be membranes to be only oblong grumous blood resembling fibres, like those that adhere to a spatula after stirring arterial blood in a basin for some time. I introduced my hand a second time, and made the experiment again, but found none of these little clots within the cavity of the womb; yet upon expanding my hand, several came out of the orifices again, which I could plainly perceive, and after keeping my hand there a little while I brought away all there were within the cavity of the uterus, and the patient's complaints immediately abated, and she recovered very well from that moment."

I have quoted this case, gentlemen, merely to illustrate the author's meaning, since the severity of the cure must almost always be a sufficient reason for our not putting it in practice. By being very cautious not to hurry the last stage of labour, and by allowing the uterus to contract and diminish its bulk as gradually as possible, we shall give the sinuses time to discharge their contents, and thus, upon the same principle as explained by Burton, we shall prevent the after-pains from being severe. It is partly to this cause that I attribute the rarity of after-pains in any degree of severity at the General Lying-In Hospital. Opiates for after-pains, which in some institutions are considered as a necessary

part of the treatment in every labour, are never given, except in cases which absolutely demand their exhibition, and this is of comparatively rare occurrence. After-pains are never more certain or severe than after a very quick labour. Upon the same principle we should be careful not to hurry the expulsion of the placenta, and to enforce that admirable rule laid down by Mr. White, of Manchester, that the patient should always sit up to suckle her child and to take her meals. Where much suffering and restlessness is produced, fifteen or twenty drops of laudanum in a little peppermint-water, or from five to ten grains of Dover's powder, will generally give complete relief.

Reviews.

Outlines of Botany, including a General History of the Vegetable Kingdom, in which Plants are arranged according to the System of Natural Affinities. By GILBERT T. BURNETT, F.L.S. In 2 vols. 8vo. pp. 518, 622. Churchill. 1835.

MR. BURNETT is so well known to the botanical world as a teacher of botany, that his name is a sufficient introduction to the present work. Botany is one of the most fascinating of sciences; it explains to us the nature of that large extent of beings spread like a rich carpet on the surface of the earth; which covers rocks, and mountains, and valleys; and which makes a wilderness a scene of admiration to the philosophic mind. It is a study of consummate delight; we reflect on the tree that contained the poor bird's nest; the beautiful plants that grow in our gardens, with all their variegated colours, surpassing all the richest painting that can be executed by art. But it contains, to the medical philosopher, treasures of higher value. Plants afford nutriment for a large majority of animals; to man they give some of his most luxurious dishes; and they contain panaceas for many of the diseases of his frame. Botany has, since the earliest records of man, been a subject of study, but, like all other branches of science, it has recently made rapid marches. The artificial arrangements of Linnæus and of Jussieu have greatly facilitated its study; they are the sign-posts to its goal, and the groundworks for its comprehension.

The present work appeared about two years ago in the form of numbers, and is now brought out in two octavo volumes. We shall present the reader with a few of its contents, and comment on them as we proceed. After apologising, in the strain of modest authors, the following are announced as deviations from the usual methods adopted by botanic writers:

"The difference adverted to chiefly consists in giving the *subjective* precedence of the *objective* view; and, considering subjective botany in general to be distributable, like other

branches of natural history, into several subordinate sciences, each devoted to the especial study of one great natural group of plants; the structure, functions, and uses of which will, collectively, form a complete, though subordinate science, as well as, disjunctively, constitute the several parts of general vegetable physics, of systematic and economic botany."

There is a semblance of pedantry about the composition of this sentence that is offensive to our ears; the same character pervades the whole work, but fortunately it is more easy, light, and amusing. There is also an attempt to elevate the science of botany higher than, perhaps, it deserves. But we can readily excuse this; an author, or a teacher, if he does not express an interest in his subject, cannot, we believe, feel it, and most assuredly will not create that sentiment in others. A few of the first sentences will convey the general character of the style:—

"(1.) Botany, superseding the ancient *herbcraft*, is the name now given to the science which relates to all those inferior ranks of the organic creation called PLANTS, or *vegetables*.

"(2.) But what is a *plant*? What do we mean by this word *vegetable*? It is a term which the most ignorant presume they understand, although the most learned are unable exactly to define; for a plant is, indeed, as Theophrastus long ago observed, 'a various thing, of which it is difficult to give a definition.'

"(3.) Tell a clown it is difficult to distinguish an animal from a plant, he will smile incredulously, and perhaps will say, 'Can I mistake *man-orchis* flowers for men?' but show him a *conferva* and a *polype*, a *lichen* and *corulline*, a *flustra* and a *flag*, or even a *mushroom* and a *medusa*, and he will at once confess, at least by silence, if not by words, that he 'kens not which they be.'

"(4.) Such presuming self-confidence in what they know, is 'the badge of ignorance and the curse of fools:' it is the humble privilege of the wise alone to doubt; and they who know the most are always the most sensible how little the most enlightened know.

"(5.) But this matter is apocryphal, not to the unlearned and the ignorant alone; physiologists the most astute have laboured, and do labour still, in vain, succinctly yet comprehensively, to define a plant. The difficulty, however, lies not so much in the perception of the differences which undoubtedly do exist, as in reducing these perceptions to the progressive scale of a still very imperfect language. The dilemma somewhat resembles that in which an ancient philosopher is said to have been involved; who, when desired to state what motion is, after much consideration, rose from his seat, walked towards the inquirer, and replied 'You see it; I can show it to you; but I cannot tell you what motion is.' Thus also, to the opening question, a botanist might answer, 'Here are plants; you see them; I

can show them to you, even if I cannot precisely tell you what a vegetable is.'"

In the first section, when treating of the "*algæ*," the subject of where life begins in matter, and what are the very lowest links of life, and of the theory of Brown on motions which are carried on in dead matter, "who has shown, by a most unexceptionable series of experiments, that locomotion, even when apparently independent of external forces, may and does exist among particles that are absolutely lifeless, nay, which have never been alive; so that, should not this phenomenon admit some more probable solution, it would seem that the long established definition, which declares matter to be inert, may perhaps require a serious modification." Mr. Burnett suspects that such motions are not active, but derived from external forces, for that if hermetically sealed between two plates of glass, so as to prohibit every obvious external action, yet that motion may be communicated in a similar manner to the expansion of bodies by heat, the insonorous vibrations of the air, and "just as many atmospheric changes are notorious with the water that are utterly inappreciable with the mercurial barometer."

Further curious, though speculative, topics are dwelt upon at considerable length, greatly so for a "*Vademecum*," or "*Outlines of Botany*." Examples of living existence in matters which were not long ago believed to be lifeless, are given.

"(41.) For example, the slimy matter often seen on rocks and stones, on hard gravel walks, and on damp walls and cellars, or on the glass of windows, garden pots, and so forth, and which is often so minute as to be lost to ordinary vision, consists of curious and most admirable vegetable structures. All the green pulverulent coating seen on old trees and palings is also found, by microscopic observations, to be composed of an infinite number of small plants, of an exceedingly primitive formation."

The observations at page 38 are abstruse reflections, but enticing much to the study of botany,—they give it its chief charms.

"(51.) Linnæus called the *algæ vermaculi*, or bond slaves, regarding them as being fettered to the rocks on which they grow. The title is particularly appropriate, and especially when applied to the lichens, which are, as it were, chained to the soil they labour to improve for the benefit of others, though from it they derive no nourishment themselves.

"The first conquests of life over death, the first inroads of fertility on barrenness, are made by the smaller lichens, which, as Humboldt has well observed, labour to decompose the scorified matter of volcanoes and the smooth and naked surfaces of sea-deserted rocks, and thus to 'extend the dominion of vitality.' These little plants will often obtain a footing where nothing else could be attached. So small are many, that they are in-

visible to the naked eye, and the decay of these, when they have flourished and passed through their transient epochs of existence, is destined to form the first exuvial layer of vegetable mould; succeeding generations give successive increments to the soil, thus forming, from which men are to reap their harvests, and cattle to derive their food; from which hereafter forests are designed to spring, and from which future navies are to be supplied.

“But how is this frail dust to maintain its station on the smooth and polished rock, when vitality has ceased to exert its influence, and the structure that fixed it has decayed? This is a point which has been too generally overlooked, and yet which is the most wonderful provision of all: the plant, when dying, digs for itself a grave, sculptures in the solid rock a sepulchre in which its dust may rest. For chemistry informs us that, not only do these lichens consist in part of gummy matter, which causes their particles to stick together, but that they likewise form, when living, a considerable quantity of oxalic acid; which acid, when by their decay set free, acts upon the rock, and thus is a hollow formed in which the dead matter of the lichen is deposited. Furthermore, the acid, by combining with the limestone, or other material of the rock, will often add an important mineral ingredient to the vegetable mould; and not only this, the moisture thus conveyed into the cracks and crevices of rocks and stones, when frozen, rends them, and, by continual degradation, adds more and more to the forming soil. Successive generations of these bond-slaves successively and indefatigably perform their duties, until at length, as the result of their accumulated toil, the barren breakers, or the pumice plains of a volcano, become converted into fruitful fields.”

Mr. Burnett's book is unquestionably not a work that will interest students, it is too scientific. Medical students, as the author is well aware (or at least the majority of them), will not devote that period to the study of the subject that it really demands. They wish but for as much botanical knowledge as will enable them to pass a creditable and general examination. With this they are satisfied. Students are the chief purchasers of such works as the present, and we must confess that, under those circumstances, we should be cautious in recommending Professor Burnett's two large and closely printed octavo volumes. Few men could have executed so talented a work. It reflects very great credit on its author, and will raise him into higher estimation in the scientific world than he even at present enjoys. The general arrangement of the book has been heretofore noticed, we shall therefore not again refer to it.

A Practical Compendium of the Diseases of the Skin, with Cases; including a particular Consideration of the more frequent and intractable Forms of these Affections. By JONATHAN GREEN, M.D. Pp. 371. 1835. Whittaker.

Dr. Green is known to the profession as having an extensive practice in skin diseases, and as having extensively employed vapour baths of various descriptions for their cure, and with what success the present production informs us. Perhaps few affections of the body are so imperfectly understood as those of the skin. Our countryman, Willan, was, we believe, the first to form a classification of their various forms, so as to reduce them to a systematic order, that they might be more readily described and comprehended. He divided them into eight orders, viz. papulæ, squamæ, exanthematæ, bullæ, vesiculæ, pustulæ, tubercula, and maculæ. These names were found to be, with but a few exceptions, descriptive of the elementary lesions of the characters which they ordinarily present. Since that period the same classification has been adopted with some but trifling modifications. Some few Dr. Green has transposed. He has removed erysipelas from the class bullæ, and placed it as an exanthematous disease; this had been done before by Bielt, who considered the vesications to be not necessarily existent, agreeing with Mr. Lawrence that erysipelas and erythema should be in the same order. The author places scabies under vesiculæ, removing it from the pustules, with some other minor transpositions, which, though not very important in practice, yet, as a philosophical classification, should be done. But these same corrections had been made by Bielt, as may be seen in his large work of 1828, published by two of his friends. The following is the author's classification of the diseases of the skin in their simple and complicated states:—

“Forms of inflammation of the skin, and diseases which appear under these severally.—Exanthema: erythema, erysipelas, roseola, rubeola, scarlatina, urticaria. Vesiculæ: miliaria, herpes, scabies, eczema. Bullæ: pemphigus, rupia. Pustulæ: variola, (including varicella,) vaccina, ethyma, impetigo, porrigo, acne, mentagra. Papulæ: strophulus, lichen, prurigo. Squamæ: pityriasis, psoriasis, lepra. Tubercula: lupus, elephantiasis Græca, cancer, molluscum, frambæsia. Furunculi: furunculus, anthrax, pustula maligna.

“Diseases which appear with the elementary characters of almost all of the above orders.—Syphilis.

“Diseases which are severally types of new and additional orders.—Pellagra, purpura, elephantiasis Arabica, cheloidea (keloide, alib.).

“Original or accidental unusual states of the skin, not referable to inflammation.—Achroa: leucopathia, (albinismus,) vitiligo. Dischroa

(Maculæ, Willan): lentigo, ephelis, chloasma, nævus.

“Diseases of the appendages of the skin; more properly of the parts which secrete and support these.—Epidermis—ichthyosis, unguis—onychia, pili—plica.”

Dr. Green is of opinion that almost all the diseases of the skin have their origin in inflammation, acute or chronic; the insensible perspiration is diminished; the skin from this deficient secretion becomes dry, harsh, and loses that smooth velvety sensation it communicates in health. In every case of acute inflammation the system necessarily participates.

Inveterate chronic diseases of the skin the author believes to exist without any derangement of the digestive organs; in this opinion he accords with Biett and some other continental writers. That disordered digestive organs is a frequent concomitant with such affections we do most potently believe. We have seen it again and again, and though we have not had such extensive opportunities of witnessing the fact as those authors, we believe it to be so. It is the system of those individuals to treat almost all skin affections by vapour baths, simple or medicated, it must therefore be their anxiety to show that local applications are the best remedies, and that physic is of little avail. We do not intend to impute this to dishonesty, or any thing like charlatanism, far from it; but there is a disposition in some men's minds to be warped by a particular theory, to ground their practice upon this, and to practise very successfully with one system, to cure nine out of ten cases, for example, as Abernethy did, of palpitation of the heart with blue pill and black draught; whilst another man was equally successful with a very different plan of treatment. In the Hôpital St. Louis, in France, the average number of baths given annually is 150,000, but internal medicines are also employed, though it must be confessed they are generally very mild, and sometimes must be inert.

Dr. Green admits the utility of purgative medicines, by acting as *derivatives* only. Sulphur has fallen in its reputation, he thinks from its being exhibited in too large doses, so that it empties the bowels and passes off before it can exert its specific influence upon the skin. Mercury he believes is highly abused in this country, we think so too. Diet drinks he regards as mere diluents. Acids he has found of great advantage, as acidulated drinks. But the great remedy is baths, they are simple or medicated, and the same title is given to the vapour of water and the fumes of different medicinal substances, as of mercury, sulphur, chlorine, &c., applied in a proper apparatus to the surface of the body. The partial application is entitled *douche*.

At the end of the work are some of the formulæ which the author is in the habit of employing:—

“*Sulphureo-Gelatinous Bath*.—℞. Sulphuret. potassæ, ℥ij—℥iv.; aquæ, cong., xxx.

Add to this solution, ichthyocollæ, lb. i.—lb. ij.; in aquæ bullientis soluta lb. x. M.

“This bath is preferable to the artificial Barége's bath, as it is neither irritating, nor apt to occasion feverishness, which the common sulphureous water bath is.

“A cheaper and not less efficacious gelatine may be procured by dissolving from lb. iss. to lb. ij. of parchment clippings in water, by long boiling, or by using a neat's or calf's feet for the purpose.

“*Emollient Bath*.—To an ordinary tepid water bath add a large basonful of thick gruel or paste, and mix it well with the water.

“One or other of these baths is often of great use in prurigo, eczema, lichen and impetigo.

“*Nitro-Muriatic Acid Bath*.—℞. Acid. nitrici, ℥ij.; acid. muriatici, ℥j. M.

“To be added to the water of a tepid bath, which should then be about as sour as distilled vinegar.

“*Liniments and Lotions*.—℞. Potassæ sulphuret. ℥ij.; sapon. mollis, ℥j.; aq. calcis, ℥viiij.; spirit. vin. rect. ℥ij. M.

“This is a good wash in porrigo especially, but is also useful in many other species of cutaneous diseases.

“℞. Liq. potassæ, ℥ij.; ol. oliv. ℥ij.; aq. rosæ, ℥j. M.

“℞. Liq. potassæ, ℥ij.—℥iv.; aq. rosæ, ℥ij. M.

“These are both of great service in cases of obstinate lepra and psoriasis especially.

“℞. Acid. nitrici, acid. muriat., āā gtt. xx.; aquæ rosæ, ℥vi. M.

“This may sometimes be used with good effect in cases of pityriasis and of chloasma.

“℞. Hydriod. potassæ, ʒss.; spirit. tenuior., ℥j.—℥iv.; aq. rosæ, lb. ss. M.

“℞. Hydrarg. chlolutet. (corrosive sublimate), gr. viii.; aq. rosæ, lb. i.; spirit. vini rectific., ℥j.—℥ij.

“These are both excellent lotions in cases of acne. They may be made with emuls. amygd. amar. instead of rose water.

“A solution of uniform strength for use as a caustic, may be prepared as a caustic:—

“℞. Hydrarg. proto-nitrat. sicc. ℥j.; acidi nitrici, ℥j. M.

“Treat the mercury with the nitric acid, and complete the solution by adding the distilled water; half an ounce is used morning and evening as a lotion in scabies, prurigo formicans, &c. It does not stain the linen. The solution of the mercury in an excess of nitric acid is one of the best caustics and escharotics we possess, in arousing indolent sores generally, and in arresting the morbid actions of phagedænic ulcers, as of lupus, &c.

“*Ointments, Cerates*.—℞. Hydrarg. proto-chlorur. (sub-muriat.), ℥j.; adipis suil. ʒiss. M.

“This is one of the best of all topical applications in lepra, and several other forms of squamous disease.

“℞. Unguent. ceræ alb., ℥ij.; plumbi sub-carbon., ℥ij.; cretæ præparat., ʒss. M.

"A useful application in the acute stages of eczema, impetigo, lichen, &c.

"R. Sulph. sublim., ℥ij.; potassæ subcarbon., ℥j.; adipis suillæ, ℥iv. M.

"Better than the common sulphur ointment in scabies."

The various forms of diseased skin are very accurately described, and as clearly as possible without annexed coloured representations. No description, however lucid, could convey the character to an individual who had not seen the particular disease. Hence the value of such works as those of Willan and Rayer, but unfortunately for many in our poor profession they are much too expensive.

FOREIGN MEDICAL LITERATURE.

REVIEW OF THE GERMAN JOURNALS.

FREQUENT variations may be observed in the health and habits of insane persons, which appear to be intimately connected with the frequent variations in the state of the atmosphere. The study of general causes is therefore very important with reference to the treatment of those affected with mental alienation; nor is it less interesting to compare the action which these general causes have at the same time on the insane, and on persons in the full enjoyment of all their faculties. Such is the object which M. Bird proposes to himself in the memoir which we are about to analyse.

His observations for the year 1831 are too brief and too scanty in detail to afford much interest; however, he remarks that the medical establishment of the House of Health did not always coincide with that of the town, and that in general the cleanly state of the hospital was more satisfying than that of Siegburg itself; but, he adds, it must not be forgotten that their exposition differs, that the establishment of the insane is situated on an elevation of two hundred and thirty feet, and the town at the foot of a hill in a humid atmosphere. For 1833, his observations extend only to July, but embrace a great number of facts worth notice. At this period the medical institution decided to act very nearly the same with respect to the insane as the other individuals. During the first six months the maladies were rheumatic and catarrhal, both of the insane and sound in mind, these latter having, however, a greater tendency to gastric and inflammatory complications, and a greater number of intermittent fevers. In the beginning of July the catarrhal and rheumatic affections disappeared, but many of the insane were subject to a relapse.

In the town, headaches became also more frequent, and it is by no means rare to see cerebral affections, often mortal, associated with intermittent fevers. But it would be endless to follow the author in the enumeration of all the facts which he observed day by day; general reflections supported by observations will suffice.

M. Bird divided the insane into two classes,—those whose brain is primitively affected under the influence of the direct exaltation of the arterial system, the maniacs. Those with whom the brain is affected but secondarily, the first pressure being on the digestive organs, venous system, thence to the arterial system and encephalous organs, the hypochondriac and melancholic.

Cold has a remarkable influence on the insane; thus during January, when the temperature was low, the weather cloudy, or when it snowed, they were all greatly agitated, but became calm as the weather became temperate. But this agitation is much increased and of longer duration in the heat of summer, tendency in the atmosphere to lightning, and, in short, under all sudden and violent changes of temperature they are ever restless and unquiet, yet M. Bird has never remarked the influence of the moon on his patients.

At the approach of spring, all nature seems to receive new life and excitation; to the insane it brings corresponding feelings; the melancholy will at first experience a certain degree of uneasiness and a passing aggravation of their state.

A young man of seventeen, who became insane at the age of puberty, and another of twenty-two, were so bad in the first five days of February, that they ate their fæces and drank their urine as a penance, one of them said, for his sins, at the same time his heart beat violently, the carotids were fuller and more stretched, while, with the exception of his head, which was hotter, his temperature did not appear to have increased.

Nevertheless, as spring advances, in the months of April and May, to their previous state of trouble and agitation succeed a state of calmness and even lucid intervals. Thus a female, continually agitated by fear and anguish, became calm, and resigned herself peaceably to work; another patient, preoccupied with sombre ideas, and whose state manifested a disposition to serenity and even some gaiety, although his melancholy has in a degree diminished, still he has again become hypochondriacal.

The state of trouble and uneasiness which appears in the first days of spring with the melancholy, is Nature's salutary effort to cure the malady; if, then, it is suitably seconded by art, a favourable result may be expected, but both fail generally; and if sometimes transient success is obtained, a relapse is to be feared in the autumn.

It is also under the influence of spring that Dr. Bird has noticed the critical secretions and evacuations, at the termination of which the state of the patient seems ameliorated, at least for some time. An idiot, forty years old, was subject to fits, during which he remained as if paralysed, appeared to have partly recovered his intelligence during March, after an abundant secretion of nasal mucus mixed with blood. Others have found relief after hæmorrhoidal fluxions, the menses long

suppressed, sweats; copious expectoration after catarrh has frequently procured salutary effect.

Favourable as the spring is in some respects to the melancholic, it is less so to the raving and those affected with hallucinations of the senses; the arterial exaltation, the immediate cause of cerebral affections, is then found to augment, delirium is then frequent with many of them, and tendency to congestion of the brain. The best season for maniacs is autumn, and the only time favourable to their cure; the contrary is the case with respect to the melancholic. Nevertheless M. Bird observes that in 1833 the arterial exaltation, cerebral congestion, and the paroxysms of raving, were less frequent and violent, which he attributes to the forbearance of all coercion, the gradual approach of spring, and in many of them to the return of long suppressed secretions and evacuations. The bath is considered by M. Bird as baneful during the cold season, but beneficial during summer.

Dr. Wagner on External Pathology.

This memoir of Dr. Wagner's resolves affirmatively a doubt long existing, namely, whether the carbuncle can be communicated by the ingestion of the flesh of an infected animal. The study of this malady, in which the Doctor has had extensive experience, has led him to conclusions differing widely from the general opinion, but as founded on experience they are entitled to attentive consideration.

M. Wagner having heard, on the 22nd July, 1834, that two persons in the village of Striesa, Prussian Saxony, had died suddenly, that many more had fallen sick, and that in one farm seven head of cattle, with several pigs, had burst, immediately betook himself thither, and has since given the following statement.

July 13th. On the herd of cattle returning from pasturage, the bull fell suddenly prostrate, and was unable to rise again. At first it was attributed to a simple wound in the back-bone; he was immediately killed, and two peasants, Stack, the gardener, aged 40, and Zeinz, the vine-dresser, aged 30, both robust men, and in excellent health, skinned, cut up, and par-took, with several others, of the flesh of the animal as food. Some days afterwards, several other animals belonging to the same farm fell sick in the same manner, shared the same fate, and their flesh was used as food by the same persons. All of them, however, quickly began to complain of uneasy sensations, heaviness in the precordial region, occasional pains in the abdomen, vertigo, &c., especially Stack and Zeinz, who had not only partaken of the flesh of the infected animals, but had handled them, and, in so doing, had been wounded in the hand.

15th and 18th. Several more animals suddenly burst. On examination the abdomen was found inflamed, the spleen gangrenous and putrescent consisted but of one membrane in

form of a sac, containing a thick, black liquid of insupportable odour; in several places under the hide, especially about the neck, were œdematous tumours. No doubt could now exist, that the malady was the true carbunculous affection. M. Wagner gives it the name of "gangrene of the spleen, *Milzbrand*," from the state of that organ as found in all the infected individuals examined; and to the septic humour which appears to generate the malady, "virus of gangrenous spleen, *Milzbrandgift*."

19th. The gardener Stack, though suffering for some days, endeavoured to walk a distance of three miles, which, with the utmost difficulty, he accomplished. Having endeavoured to recruit his feeble state with a draught of malt liquor, he made an effort to return, but was seized with vomiting, pains in the abdomen, and fell prostrate on his back. He was carried home; icy coldness of the extremities, thence to the trunk, supervened; diarrhœa of black liquefied blood; convulsive movements of the head and limbs; legs blue and livid; nose sharpened; eyes hollowed; with great suffering in the abdomen, and repeated vomitings; but death relieved him on the 20th.

On the same day, the widow Gaertner was affected much in the same manner; a black pustule also had appeared on one of her thighs. She was found dead in her bed on the following day, with a child still sleeping beside her and in perfect health. On the 22nd the decomposition of these two bodies was advanced nearly to liquefaction, and, therefore, precluded examination.

22nd. Nine other persons who had either come in contact with the infected animals, or had eaten of their flesh, were attacked with the epidemic; general symptoms and sufferings nearly the same in all. The vine-dresser, Zeinz, had a black pustule developed on the outer side of the thigh, but, with the exception of the sensations arising from this, he did not suffer more than the rest. As the malady with most of these persons had already been of some days' duration when M. Wagner arrived, he found no indications requiring vomits. To the necessitous who were yet free from anthrax, he administered the most simple remedies; cataplasms of linseed and flour of bran in white wine vinegar applied to the præcordial region, infusion of tiglia, or simply water acidulated with white wine vinegar, to promote and sustain a moderate perspiration; abstinence as far as possible. With those in easy circumstances, and with those, also, in whom carbuncles were developed, a more active treatment was necessary. An incision cross-ways was made in the pustules, and, with respect to Zeinz, to the depth of half an inch, cauterised, and the wound sprinkled with strong caustic potass. During nearly the whole operation he was insensible, but was at length painfully conscious of a pricking and burning sensation; the gangrenous scab, which was hard and dry, softened and sunk; a cataplasm of linseed and powdered oak bark in white wine vinegar was

applied; small doses of camphor, and a strong decoction of quinquina mixed with a little of Hoffmann's anodyne liquid mineral.

24th. All the infected were better except one, an old woman, with a pustule on the thumb, which had been cut and cauterised. Every symptom aggravated; the whole arm swelled and inflamed to the shoulder; the fore-arm covered with reddish-blue vesicles; face red and burning; intense fever; diarrhoea; extreme prostration; skin dry and hard; sweetish taste in the mouth. Considering this case as altogether hopeless, M. Wagner only applied a cataplasm of new cheese to the wound.

In place of the gangrenous scab on the thigh of Zeinz was a hollow, half an inch deep, circular and blackish, edge narrow and red; fever gone; appetite, strength, and spirits returned. This rapid amendment was preceded by a general and profuse sweat of infectious odour. The wound was sprinkled with quinquina and caustic potass, dressed with le Baume Arcæus, and recovered with the vinegared cataplasm; internal treatment as before.

29th. Sensibility restored to the infected member, but the gangrenous hollow was of twice the depth, and no separation could be discerned between the unhealthy and the sound. It was now dressed with powdered quinquina, balsam of Peru, brown ointment mixed with myrrh and camphor, and again covered with the vinegared cataplasm.

Aug. 1st. The gangrenous sloughs separated with the bistoury, the wound being three inches in length, two and a half in circumference, and three quarters in depth, of a clear red, and secreting laudable pus.

5th. Begins to be covered with fleshy pimples and granulations of good appearance.

11th. The whole excavation filled with them; occasional torpor in the feet, followed by a pricking sensation.

14th. Cold tumefaction of the integuments of the limb extending to the abdomen. Application *de sachets de son chauffés*; the fleshy pimples have pustulated to such a degree as to require the use of the potassa fusa.

18. Tumefaction subsided; cicatrisation of the wound beginning, and will, no doubt, be soon completed.

The old woman, whose case had been considered as utterly hopeless, two days afterwards rallied considerably, to the great astonishment of M. Wagner. No critical perspiration had here supervened, but the diarrhoea was so excessive as to pass without consciousness. The gangrenous pustule was suppurating: the vesicles on the fore-arm had sunk, and the swelling subsided from top to bottom. Same treatment external and internal as in the preceding case. The general state of amendment proceeded, and so rapidly, that on the 29th of July she could walk above a mile. The local affection was more tardy; the pustule extended all round the thumb to the back of the hand; the scab, though superficial, was hard, horny, dry, and black, and when a part

of it detached itself a few days afterwards, the suppurating surface beneath emitted a foetid odour. It was dressed with powdered quinquina, and shortly afterwards bore a favourable appearance, and thus continued to do; and on the 4th Sept. the cure was completed.

On the 6th of August two more patients had presented themselves, after a lapse of eight days, during which no case of infection either in man or brute had occurred, and while every precaution was in use to prevent the spread of the epidemic. They were two fellow-servants on the same farm, the one 26, the other 50 years of age; and though they had been many times in contact with the infected animals, they had never eaten of their flesh. The elder woman it appears had, while standing beside the infected old woman above mentioned, been stung by a fly in the inner side of the left arm. The little puncture became painful, swelled, and inflamed, and at length assumed the appearance of a dry and livid pustule. The younger woman could not give so decided an origin to the pustule formed on the outer side of the right arm, which was surrounded with gangrenous vesicles, swelled and inflamed from the elbow to the shoulder; but it is necessary to state, that the hide of an infected animal had been found in her chamber. Might not this have been the origin? Might not some particles of the flesh or cellular tissue have been still adherent to the skin, and in its recent state have attracted the flies, whose puncture would then most certainly transfuse the virus? Such facts have been before observed, and examples of them are cited by Bertrandi and Monteggia.

Recourse was had to the same internal treatment as in the preceding cases; but as it was too late to incise the carbuncles, and M. Wagner having found that cauterisation after incision extended the gangrene, he only applied cataplasms of new cheese, or of bran and linseed. The internal remedies were also soon changed, and a beverage of curdled milk substituted, mixed with water, or an infusion of tiglia.

The young woman's fever was of an inflammatory character; and pains in the chest supervening she was bled in the arm. The state of the pustule rendering the application of caustic potass necessary, it was tried, but soon removed, the pain arising from it being too excessive to be borne.

On the 13th of August, after profuse perspiration, the general symptoms, and also the swelling and inflammation around the pustules, subsided with both the patients.

Three weeks after the first appearance of the epidemic, another and fatal case of infection presented itself.

A young man, 20 years of age, servant on the same farm with the females above mentioned, had not only handled infected animals, but had eaten of their flesh. Nevertheless, he continued in good health for a fortnight after the first appearance of the malady; he

was then seized with all its symptoms; a pustule on the forepart of the left arm spread an inch and a half in two days. Profuse sweat amended all symptoms for a short space, but on the 18th they returned, and with such violence, that on the evening of the same day he breathed his last.

In two villages adjacent to Striesa a few isolated cases of the infection were at the same time observed. Four men, in the prime of life, who had not only been in contact with infected animals, but had partaken of their flesh as food, were seized with all the symptoms of the epidemic, but recovered in the course of three weeks.

The following experiment is noticeable. Some fat of an infected animal was melted and thrown to two pigs, two dogs, and two cats; all of them burst while rolling on the grass, which they appeared to do for relief.

From the foregoing facts the author draws these conclusions:—

1st. That the strength, more or less, of the malady depends not so much on the presence, number, and size of the pustules, as on the concomitant fever; the pustules being but a product or symptom of the malady, and may be altogether wanting, and the fever still exist.

2nd. The carbuncular, or splenic fever, with or without pustules, does not propagate itself by means of miasma in the air, but communicates itself by the ingestion of the flesh of infected animals, by contact with them, and by cutaneous absorption. The animal virus, which appears to be the principle of the malady, is fixed, unalterable, not to be decomposed by any process, as the foregoing statements prove.

3rd. Whether the pustules be excised, cauterised, or not touched at all, the concomitant fever and inflammation proceed in their course, and the duration of the treatment is in no degree abridged; but experience demonstrates that violent measures oppose the curative efforts of nature, and may prolong the malady. If the infection be received internally, excision and cauterisation are useless; if on the exterior surface they are only useful in the first state of the pustule, when yet very small; and it is rare that medical assistance is then sought. The topical remedies which proved most serviceable to M. Wagner were, warm emollient cataplasms, or those of new cheese, powdered quinquina, alone, or mixed with powdered charcoal. It is doubtful whether the administration of quinquina and camphor internally be really useful. But, under whatever treatment, the pustule remains ordinarily from four to six weeks; when the infected die it is frequently during a febrile paroxysm. In a slight attack, a vomit has often proved completely efficacious. Milk drunk in great quantity after the ingestion of the infected substance is of use by provoking sickness and vomiting.

M. Wagner attributes the frequency of carbuncular affection, so observable in summer

in the Circle of Schweintz, where he practises, to the great number of pools and ponds of stagnant and filthy water in the vicinity of the Elter, and which evaporate during the great heats.

Reports of Societies.

ZOOLOGICAL SOCIETY.

Tuesday, February 24th, 1835.

WM. YARRELL, ESQ., in the Chair.

A PAPER was read by — Owen, Esq., entitled “A Description of a Microscopic Entozoon infesting the Muscles of the Human Body.”

As the cases, in which these worms have been observed, do not appear to have betrayed any discernible symptoms during lifetime, it would prove of no avail to our numerous readers to detail them. Our author found, on examination, that the whole of the voluntary and semi-voluntary muscles were studded with innumerable white tough specks. These were discovered to be cysts of an elliptical figure, with the extremities generally alternated and more opaque than the body of the cyst, which is sufficiently transparent to allow of a minute coiled-up worm being seen through it. The cysts measure about $\frac{1}{50}$ of an inch in their longitudinal, and $\frac{1}{100}$ in their transverse diameter, and they are generally placed in single rows, at a distance varying from half a line to one line apart. The worm, when removed from the cyst, was usually found to be disposed in two or two and a half spiral coils. When straightened it measured from $\frac{1}{25}$ to $\frac{1}{30}$ of an inch in length, and from $\frac{1}{700}$ to $\frac{1}{800}$ of an inch in diameter. The worm is round and pilliform, terminating obtusely at both extremities, which are of unequal size, and tapering towards one end for about $\frac{1}{3}$ of its length, but continuing of an uniform diameter from that point to the opposite extremity. At the greater extremity a large transverse linear orifice is observable. At the lower extremity no vestige of an orifice could be detected. No alimentary canal or any internal organs were apparent. The structure consisted intirely of a minute transparent external skin, containing a fine granular flaky substance, or parenchyma, highly fragile. There is no projecting spiculum, or hook, observable at either extremity, nor is it discernible that the worm had been torn from an attached cyst.

Mr. Owen made some observations on the value of the genus *Capsularia*, Zed, a genus rejected by Rudolphi, who distributed the species, comprehended under it, into *filaria* and *ascaris*, worms so highly organised as not to admit of the simple form in question being arranged with them. Its simplicity of structure, and the situation in which it occurs, connect it in some degree with the order *cystica* of Rudolphi. But to that order it

cannot be referred, as it does not possess either the complex formation of the head, or the dilated vesicle of the tail. It ought, therefore, to be regarded as representing a new order; the position, however, among the entozoa cannot satisfactorily be settled in the present condition of that class, which is, as now constituted, any thing rather than a natural group. In fact, the new form appears to be even more nearly allied to the vibriones of Muller than to any internal worm hitherto noticed. Mr. Owen, however, refers it only provisionally to the entozoa, and regards it as the type of a genus to be designated *Frichina*, which he characterises, as well as the single species included in it, under the name of *Frichina spiralis*.

Mr. O.'s paper was illustrated by a series of drawings.

WESTMINSTER MEDICAL SOCIETY.

Saturday, February 25th, 1835.

Dr. ADDISON, in the Chair.

Umbilical and Inguinal Hydrostatic Trusses
—*Aphonia*—*Headachs*.

Mr. Mart exhibited an umbilical truss, constructed on hydrostatic principles; the water was contained in cells around the circumference of the pad, and also in an elevation corresponding to the navel, the cavities freely communicating; it was admitted by means of a valvular opening. The principal advantage expected was, that if the abdominal muscles should compress the circumference of the pad, during their action, the fluid would be forced into the nipple-like process opposite the navel, and thus more completely restrain the hernia. The contrary was the case with the inguinal truss; the pressure is exerted on its centre, instead of its circumference, during the action of the abdominal parietes, and hence the instrument is so contrived, that when the centre is compressed the fluid is forced into the cells of the circumference, thus giving additional support to the hernia. Mr. Mart remarked, that, with these instruments, it was a moral (query, physical) impossibility that the hernia should escape.

Dr. Leonard Stewart afterwards narrated a case of aphonia of four or five years' standing, and which had resisted the various plans of treatment tried by several distinguished medical men. Dr. S. mentioned the case to Dr. Webster, who recommended the application of leeches to the head, as he considered it to be dependent on pressure on the nerves of the larynx, and so interrupting their functions. The leeches were applied, and when they had dropped off the patient fainted; in the course of that night she fully recovered her voice, which she has since retained. The Doctor considered the disorder was dependent on congestion in the head. Disease in the head pa-

ralysed the extremities, and from the same cause Dr. W. thought the organ of voice might be affected.

Dr. Webster stated his reasons for recommending the application of leeches to the head, and he believed this plan of treatment was more especially applicable when the aphonia was accompanied with fulness of blood and pain in the head, dimness of sight, deafness, &c.

Dr. Stewart observed, that in his patient he had no suspicion of head affection, since the countenance was not flushed, nor the pupil dilated, nor was there even headach, and the patient was not plethoric.

Some observations were then made by Dr. Johnson, Dr. Webster, Mr. Greenwood, and others, relative to other forms of aphonia; the opinion appeared to be general, that when the symptoms, mentioned by Dr. Webster, were present, the plan of treatment recommended by him would be highly beneficial. Dr. Johnson remarked, that loss of power in the muscles, or the nerves, of the larynx, did not necessarily depend on cerebral congestion, but might arise from sympathy with other organs, and he thought such cases might be speedily cured by purgatives and tonics.

Dr. Webster, after a few preparatory remarks, then proceeded to make some observations on headachs. He stated, that on the present occasion he did not intend to embrace the whole subject of headachs, but confine himself to the consideration of two kinds; one affecting the forehead, called *megrin*, and generally dependent on a disordered condition of the stomach and liver; the other situated in the back part of the head, owing its cause, as he considered, to the colon or rectum.

When the forehead is the seat of pain the usual symptoms are, flushed countenance, throbbing or pain in the temples, foul tongue, and sickness, with loss of, or impaired, appetite; when the stomach is less affected, the appetite may be good, and the tongue clean. Accompanying these symptoms there is frequently giddiness, which may be considered as indicative of disordered liver. Giddiness is frequently the precursor of jaundice, and it is rather remarkable, that the treatment which relieves the liver, and restores its functions, will remove the giddiness.

The treatment of headach affecting the forehead should be directed to clear the stomach, and promote the secretion of the liver, at the same time leeches may be advantageously applied to the forehead and temples, and recourse may be had to a blister if necessary; when the back part of the head is affected, aloetic purgatives should be given, and enemata employed, and a blister to the nape of the neck, or a seton, may be useful. In either case strict attention to diet and regimen is necessary. In treating headach large cuppingers are frequently had recourse to by practitioners, but, unless there is great fulness and determination to the head, Dr. W. does not think it

advisable, and he has seen it often produce injury instead of benefit. Where the headaches were of an intermitting character, after proper regulation of the digestive organs, Dr. W. found quinine to be a most useful remedy.

Rather a desultory but prolonged conversation took place on this subject, of which we must be contented with giving the heads.

Dr. Johnson inquired of Dr. Webster if he could tell him what was the seat of pain in headach?

Dr. Webster considered the question a very difficult one to solve.

Mr. Horne alluded to some cases of diseased kidney which had been under his care, and in which there was an evident connexion between the renal disease and a continued headach, to which the patients were subject.

A gentleman, whose name we could not learn, stated that the headach, arising from intense mental application, and which was peculiar to literati, was best relieved by equalising the circulation, through the medium of the warm-bath.

Mr. Greenwood considered thickening of the cranium was not an unfrequent cause of periodical headach. He believed that it was sometimes difficult to form a diagnosis as to the origin of the disease, whether dependent on disorder of the stomach or of the head; but, perhaps, it would be best obtained from the treatment, as activity of the body, exertion of the mind, warm rooms, and stimulating food, would relieve headachs caused by disordered stomach, but aggravate those arising primarily from the head.

Dr. Johnson mentioned the case of a lady, a patient of his, in Sloane-street, who has been the subject of periodical browach for the last three months, which has continued in spite of every thing that has been tried. It arose in the first instance from mental agitation, from the death of a favourite daughter. It commenced regularly at 1 A.M. and continued without intermission until 6 A.M. The patient compared her pain to that resulting from the application of a red hot iron.

Dr. Leonard Stewart mentioned, that at one part of his life he was the subject of severe hemicrania for seven months, and nothing proved of any use until, by the advice of Mr. Abernethy, he took sarsaparilla, and he then got quite well.

Dr. Webster considered that pain of the back of the head might be fairly attributed to disorders of the large intestines, as he had seen it come on so long after the ingestion of food, that it must have passed into the colon, and also because those purgatives, which are considered to act especially on that part of the intestinal canal, prove most effectual in relieving the complaint.

Some further remarks were made on headachs following great hæmorrhages, consequent on the evolution of gas in the intestines, sympathetic of disease of the spinal cord, &c., after which the meeting adjourned. In the

course of the evening some observations were incidentally made, relative to the sensibility of the cerebral mass in health and disease.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

March, 1835.

HENRY EARLE, Esq., F.R.S., President, in the Chair.

After the preliminary business of the preceding meeting was settled, and the new President had thanked the members for the unexpected honour that had been conferred upon him, he expatiated at no inconsiderable length on the grant of a royal charter, recently conferred; and on casting his eyes around, and beholding the valuable records of medical literature, which, although they reminded him of the "handwriting of yore," nevertheless plainly foretold, that by the assistance of the members, and the gentlemen who attended as visitors, with their communications, which would tend to extend these valuable Transactions, the Transactions of the Medical Chirurgical Society, which contain a greater proportion of facts, their size considered (having now extended to twenty-three volumes), than any other medical transactions in the world, the Philosophical Transactions excepted, would continue to prosper, instead of a limited time, for ever. (*Applause.*)

The Secretary then proceeded to read a paper, entitled "Observations on the Functions of the Fœtal Kidney, by Robert Lee, M.D., F.R.S. The author commenced by observing that in the works of systematic writers on physiology little or no information is adduced respecting their functions prior to birth.

Dr. Lee, in the course of his very excellent and, it must be confessed, unique paper, brought forward various facts, which he considered to demonstrate that the fœtal kidneys, like the intestinal canal and thymus gland, are in a state of activity, and perform the functions allotted to each previous to birth.

It seems that our author was indebted to the conclusions which he has arrived at, to the following illustrative case. A fœtus of eight months, still-born, with both ureters impervious and the kidneys distended with urine; the left kidney contained four ounces and the right nine ounces of a fluid, which he submitted to Dr. Prout for analysis. The fluid was found to hold in solution both urea and uric acid. (*Some crystals of uric acid were exhibited.*) Hence Dr. Prout concluded that the fluid was most decidedly of an urinary nature, a fact, he observed, which had often before been suspected but never demonstrated.

Dr. Lee induced premature labour, the patient six months advanced, pelvis deformed, and obtained thirty-two ounces of pure

liquor amnii, in which neither Dr. Prout nor Dr. Bostock could detect urea or uric acid in its composition. This led our author to remark that it is probable that at this early period a small quantity only of urine is secreted, and passes from the bladder to mingle with the liquor amnii.

In further proof of the opinion that the kidneys secrete urine anterior to birth, the Dr. quoted a case of impervious urethra, from Mr. Howship's work on Diseases of the Urinary Organs, also a second case, which came under the observation of Sir B. C. Brodie, and two others, related by M. Billard, of malformation of the foetal kidneys and obliteration of the ureters.

Mr. H.'s preparation, and two drawings exhibiting an anterior and posterior view of it, well executed, were exhibited to the Society, and also the preparation that the Dr. obtained the history of his case from was shown, which gave rise to a long and very interesting discussion, such as we believe has not lately transpired among its members. The President, the author, Dr. Simms, Dr. Burne, Mr. Howship, Mr. Partridge, and Mr. Thompson, entered *con animazione*, into the subject.

LONDON MEDICAL SOCIETY.

Monday, March 16th, 1835.

DR. WHITING in the Chair.

Mr. Stephens presented to the Society specimens of some small urinary calculi, voided in prodigious numbers from a female patient, who, two years antecedently, had undergone the operation of extraction, and since which period she had suffered from incontinence of urine. Mr. Stephens considered the calculi uncommon, and worthy of the Society's notice, for, on examination, he thought the nuclei would prove to be hair, which was found to be correct as far as regarded those calculi which were imperfectly formed, but those that had assumed the shape and size of a pea, did not present that phenomenon. The discussion which ensued bore reference solely to the possibility of the hair being introduced artificially into the situation in which it became the nucleus of the stones.

Mr. Kingdon considered that its presence might be caused by the incessant friction to allay the immense irritation that must necessarily be constantly present, thereby causing their lodgment in the meatus urinarius.

Dr. Clutterbuck considered that the nuclei being formed of hair, originated from the urine involuntarily passing from the patient, and forming externally from the varied shape of the concretions; and suggested the propriety of eliciting more minutely, from the patient, facts bearing on this essential point.

Mr. Clifton could not agree with Mr. Kingdon as to the possibility of the hair becoming the nuclei while in the meatus urinarius, as

the constant stilloidism of urine that was going on would tend to their dislodgment; but would rather concur in the opinion given by the learned Doctor.

The President requested to know whether any members present had met with any cases that coincided with those he had related to the Society at a previous meeting, as a similar one had since occurred in his practice, where the whole cutaneous surface was so exquisitely sensible, that it could not bear the least impression made on it, without the patient evincing excruciating pain.

Mr. Kingdon remarked that he had lately met with a case which brought to his recollection the cases referred to by the President, where it would seem, if any assignable cause could be given, that it arose from the effect of exposure from a warm to a cold temperature, as the patient, an elderly gentleman, possessed a peculiarly sensitive constitution.

Mr. Kingdon afterwards narrated the case of a lady who had been married when very young by the desire of her parents (who were perfectly free from any cancerous diathesis) to a rich old gentleman. She died childless at the age of 40, of a malignant disease affecting both breasts, which at one period assumed the characters of genuine fungus hæmatodes, at another the tuberculous sarcoma of Abernethy. Prior to death they digressed, but manifested to an equal extent their malignant virulence. At the post mortem examination the muscular substance of the right side particularly was found almost entirely destroyed, there being scarcely any traces left of the pectoral or intercostal muscles. The ovaries were enlarged, and, together with the lumbar glands, were implicated in the morbid derangement.

Several members advanced various hypotheses for the rationale of the commencement and progress of the complaint, which it would avail but little to transcribe to our pages; but, without leaving the case thus abruptly, we, as honest and impartial journalists, would remind the members of the power of the sensorium, in a state of disease, producing baneful effects on the uterine system, where the functions of the latter have not been exercised through inability, as in the above case, causing disappointment and grief, frequently manifested during the life of the patient by the temper becoming peevish. Judging from the cases that have fallen under our notice, similarly affected, we have invariably found that the breasts became the seat of the disease where the uterine organs have not been brought into action; but, on the other hand, where the disease occurs after pregnancy, the matrix, and not the mammæ, is the part affected.

REMARKS ON THE CONSEQUENCES
OF PHLEGMASIA DOLENS, MORE
ESPECIALLY WITH REFERENCE TO
THE NERVES AND SPINAL MAR-
ROW.

To the Editors of the London Medical and
Surgical Journal.

GENTLEMEN,—Having in my last communication (inserted in No. 162, page 171, of your valuable Journal) attempted to point out the proximate and exciting causes of phlegmasia dolens, before quitting the subject, I think it my duty to allude briefly to a most disheartening train of symptoms that sometimes suddenly springs up after the phlegmasia has apparently subsided, and which I do not find that any writer has taken the least notice of; not that I conceive for a moment that the same termination of the disease has occurred only in my own practice, but probably, as ably remarked at a late meeting of the London Medical Society by its president, Mr. Kingdon, our attention having been attracted by any particular symptoms, we are on the *qui vive* for their very next appearance. The change I allude to is the following. The pain suddenly leaves the affected part of the extremity, and is experienced darting towards the pelvis, and as the inflammation (satisfactorily evident by the pain) rapidly extends up the spine, the nerves, along with the spinal marrow, become implicated. When the inflammation has extended to that portion of the cervical column, which gives off the phrenic nerve, the severity of the patient's sufferings is now principally confined to the thorax. Respiration becomes exceedingly oppressed and painful, with a distressing hacking cough, and palpitation threatening constant suffocation. The functions of the brain are more or less affected, according to the condition of the fever, whether inflammatory or typhoid.

With respect to the treatment, I am fearful it will be proved that our efforts will be seldom of much avail. Should it be considered expedient to reduce the system, it must be attempted with great caution, for after a very moderate venesection I have noticed, in two instances, sudden collapse ensue, in which state the patients have soon expired, without the slightest efforts on the part of the constitution to rally, although aided by powerful stimuli. Experience has now taught me to rely on opiates and diaphoretics, and abandon all thoughts of depletion.

From the symptoms we are led to expect, *a priori*, considerable mischief in the cavity of the thorax at the post mortem, but the reverse will be found the case. The lungs and heart, provided they were previously healthy, will now be found perfectly sound, (as is not unfrequently the case on opening children who

have died of hooping cough, or rather of its effects on the brain and spinal marrow; the cerebral and spinal excitement terminating in an effusion of serum producing convulsions and death).

In the two cases which proved suddenly fatal, and which were alluded to when offering a cautionary remark as to bleeding, the only detectible morbid appearance was ramollissement of the spinal and cerebral mass. No doubt the same condition had affected the nerves, although it could not be so clearly demonstrated.

I am, Gentlemen,
Your obedient and obliged servant,
J. H. HORNE, Surgeon.

5, Gerrard-street, Soho,
9th March, 1835.

HOSPITAL PECULATION.

To the Editors of the London Medical and
Surgical Journal.

GENTLEMEN,—I am one of those who, trusting to the good faith of implied engagements, paid some six months ago the sum of twenty-five guineas into the hands of one of the principal surgeons of St. Bartholomew's Hospital, for the privilege, as I then understood, of profiting by seeing the surgical practice of the hospital under his auspices. Being an ardent lover of my profession, I attended ticket in hand, and big with the hope of witnessing "sound chiro-surgical" instruction at the wards. But lo! what was my disappointment, when, instead of being the auditor of acute investigations into, and grave observations upon, the different cases, which I expected, I found myself, after waiting at one of the doors until 1, P. M., in the rear of some forty fellow students, following in double quick time the steps of our preceptor from bed to bed. Case after case disappeared, and no profound observation met my ear, nor could I indeed get a sight of the sick patient. No stop, no stay; on, on we steered, and only a few hardened pupils out of our regiment could keep up with our Mentor; these lucky ones rallied round him, and closed all access to the patient's bedside. As I came up in the rear with ears pricked to catch something, away scudded our preceptor, and I was obliged to give chase again, till breathless, and squeezed, and disappointed, I found my fondly cherished hope of instruction vanish day after day into thin air. Being of a hot temperament, I was hardy enough to propose to some fellow pupils to call a meeting for the purpose of remonstrating against this unseemly despatch of business, but got laughed at for my pains. I attended on operating days, got into the theatre one of the first, and congratulated myself upon a sort of victory over villainy. But behold! again there was no sight for me. A phalanx of dressers and other privileged specials occupied the floor surrounding the operating table, and although vociferously

called upon by myself and unlucky comrades to keep their heads out of the line of vision, they persisted in obstructing our view. What most of us got was the delectation of hearing the patient roar, seeing a knife brandished, a bloody sponge or two passed over head, and, finally, the sufferer carried off, shorn of one of his nether limbs; but no glimpse of the affair of separating it saluted my optics. After several unsuccessful attempts in this way, I was told, unless I became a dresser, at the additional expense of twenty-five guineas, I might despair of gratifying my desire for knowledge. To you, gentlemen, as the expositor of abuses, especially such as are calculated to damp the ardour, and injure the prospects, of a young aspirant in the profession, I have finally resolved to address myself, and respectfully trust you will, in some way or other, as seems best to you, notice my complaint.

I am, Gentlemen,

A DISAPPOINTED BARTHOLOMEW STUDENT.

THE

London Medical and Surgical Journal.

Saturday, March 21, 1835.

THE HOSPITALS AND THEIR REGULATIONS.

IN surveying those magnificent structures, which the philanthropy of Englishmen has caused to be erected for the restoration of health to the afflicted, a deep impression of the charitable feeling of the people is conveyed to the mind of the spectator. He contemplates with admiration the liberality which could part with so much wealth even for so estimable a purpose, and enters the hospital portals expecting to find the internal management and regulations, in every respect, correspondent to the external aspect.

At the first *coup d'œil* he meets no disappointment, his eye scans cleanliness, order, and comfort. Of course he blesses his stars that there exists so much philanthropy, so much unalloyed good in this world of evils. But let his inquiries be directed a little farther, let him, taking for granted that the neatness and order which meet his view are the effects of an excellent economy, be sufficiently curious

to examine into the more important machinery of the establishment, and his curiosity will be gratified at the expense of his former approbation,—leaving the demure-looking sisters, the clean aproned nurses, and burly porters on one side, let him take a review of the *corps d'élite*, the health officers who serve the institution. These he would find distributed into head surgeons, their assistants, and apothecary, house surgeons, and dressers. Let him, we say, take a review of this corps, and he would marvel that, within this apparent *terra firma* of charity, extortion and speculation flourished abundantly.

Such an inquirer would find, in the course of his investigation, that the head, or principal surgeons, received an enormous remuneration; not from the funds of the establishment, but in fees from students resorting to it for information. He would find the assistant-surgeons touching no reward in the aforesaid way, but waiting for their turn to do so in succession, as their Gamaliels became defunct, or retired from the field. He could not fail, nevertheless, to perceive that a certain harvest was reaped by them in the interim, owing to the prominent situations they held. The apothecary might perchance be in his shop and so escape scrutiny, but the house surgeon would be looking sharply after some hospital assistancy, or infirmary, and paying for standing on his elevation. Lastly, the dressers would pass in review; each in his own estimation a profound “chirurgical,” but *nevertheless* paying for his post. After these would follow a promiscuous phalanx paying for being the witnesses of the feats of all the former. All this would our inquirer behold, and he could not fail to feel surprise that, in the house of charity, *payment* in some way or another was the order of the day,—patients excepted, all

parties would be fingering cash, either in receipt or disbursement.

Looking at the amount of money collected from house surgeons, dressers, and forlorn-looking students (we speak of a large hospital), our friend would say, "Here is money enough to support this glorious establishment extracted out of the pockets of those who avail themselves of the advantages it presents for acquiring knowledge,—doubtless the pelf is appropriated to that laudable purpose." The rejoinder would be "No! two or three principal 'chirurgicals' pocket all, leaving their assistants the hope of doing the same at some future period." The inference he would draw from this exclusive dealing would be "either these head surgeons are men of indefatigable exertion, and almost supersede the necessity of their unpaid helpmates, or they are the foremost of the eminent, a sort of magicians in their art!" What beadle or porter in a hospital would not smile at this conclusion? Not because it bears any thing extravagant in itself, but because the misapplication of the funds in question has been so long continued, that what is unjust and monopolising on the face of it, has been rendered indistinct and obscure by the rubbing of long usage.

Disappointed at finding disinterestedness among the heads, the assistant surgeons receiving nothing, and chewing the cud of *hope*, would engage his attention, and probably his wonder at the eagerness with which men sought and contested for that office. He would say, "here are charitable gentlemen, active and good, struggling to be employed in what brings them no remuneration—men doing good for its own sake!" But as disappointment when begun is apt to recur, so would it here. The disinterested assistant would be found rioting on loaves and fishes,

which his attachment to a hospital procured him, by advancing his private practice.

Our inquirer would then demand, with a rueful face, what sacrifice of time and labour functionaries so well paid, both directly and indirectly, bestowed upon their studies? The answer, we opine, would yet lengthen his visage, "a very trifle, no more time or labour than is compatible with an extensive private practice; to which, indeed, they all bend their principal attention and energy. With a few solitary exceptions they deliver no clinical lectures, by which to enlighten their juniors, the *paying* students; nor visit the bedsides of the sick oftener than once a-day unless upon some great emergency." We now quit our friend to make a few observations.

Students, paying at the rate of 25 guineas each to the principal surgeon of a hospital for their instruction, are permitted to follow the heels of the latter through the different wards,—from 100 to 200 at least do this at a large hospital annually. It is plain, that so great a number cannot, as things are now conducted, derive much benefit from their *soi-disant* instructors in what is called hospital practice. For how can even a fourth part of the number of students witness the conduct, or hear the opinions of the surgeon, at the patient's bedside? Ten or twelve get close to him, surround the bed, and exclude the rest from perceiving what is going on. The celerity, too, with which the business of visiting the sick in hospitals is performed, adds to the pupils' difficulties. Now, the only mode in which the surgeon could repair this error, in receiving more than he can give a fair equivalent for, in the ward-hunting business, would be by delivering, daily, clinical lectures in the theatre of the school, where there would be

accommodation for all,—an hour at least, daily, should the surgeon lecture. But, as this is not done, and has not been done, it is clear, that the money they extract from the students for hospital practice is taken for nothing. In fact, in no other profession is the quackery of tuition carried to so great a height, nor the moral ties between teacher and pupil so scandalously violated on the part of the former. In no transaction, where obligations are purchased with money, does the fulfilment of the contract sit so loosely on the receiver of the money. Yet *these receivers* are, in our profession, the parties who lord it over the rest. *They*, one after another, fill the Council and Court of Examiners of our College of Surgeons. They are the men who *first* opposed the appointment of a Medical Committee in the House of Commons, and *now* will, after their defeat in that attempt, essay every stratagem in their power to crush the good its Report may produce when brought up. But if Medical Reformers stand together, if they hold themselves prepared to meet and discuss the means of emancipation when the proper moment arrives, the good cause shall triumph, and their wonder arise why they essayed not the victory before.

In the meantime to such as luxuriate in the almost sinecure offices of principal surgeons to our hospitals, we recommend that, for the sake of decency, they enlarge the scope of their usefulness to those who pay them so liberally; that they abolish the office of dresser, and permit, without an additional fee, every pupil in his turn to take the care of patients under their superintendence; that they deliver a clinical lecture on the cases under treatment, of one hour's duration each day—and thus endeavour to atone, as well they may, for charging the sum of twenty-five

guineas for attendance at the farce of walking, or rather running, after them through the hospital wards.

UNIVERSITY OF LONDON.

ON Tuesday, the 17th instant, Mr. Tooke, in his place in the House of Commons, moved for a copy of the charter of incorporation applied for by the University of London in 1831, and the steps that had since been taken with respect to it.

In answer to a question from Mr. Warburton, who wished to know whether the Hon. Member (Mr. T.) proposed in his bill to give the University of London the power of conferring medical degrees, as if he did so, he (Mr. W.), although a member of the council, was resolved to oppose it, Mr. Tooke stated, that understanding there was reason to suppose that a medical board would be constituted in London for the purpose of examining all candidates, and conferring degrees in the various branches of medicine and surgery, to which all the schools would be subject, he apprehended that the University of London would be recommended to agree to a restriction as to the power of conferring degrees in medicine as well as in divinity.

Mr. Roebuck stated that he would, on the part of the Dissenters of England, demand, that in case such a restriction was made with regard to the University of London, it should also be extended to the Universities of Oxford and Cambridge. The Dissenters had a right to perfect equality on the subject. He hoped, therefore, that his Hon. Friend would not withdraw that clause in his bill until there was a clear understanding that the other Universities would be placed on the same footing. The motion was agreed to.

**ON THE FILTHY SUPPLY OF WATER
TO THE METROPOLIS AND ITS DE-
LETERIOUS EFFECTS.**

Aqua, splendor vitæ !
Quando te bibam ?

SUCH may well be the exclamation of a resident in our metropolis, whose muddy beverage, after pursuing its lazy course through quagmire and bog, finds its way at last into his culinary utensils, an opaque or only semitransparent fluid, thence to be decanted into his stomach, vitiating its functions, and slowly but surely impairing the springs of life. The crystal stream seldom sparkles in his cup, unless drawn from one of those wells or pumps too rarely distributed in our dusty Babel to be of any general utility. Yet nothing can be plainer than that our very existence is intimately connected with the good or bad qualities of an element so constantly in requisition, and that to obtain it pure should be the especial care of a legislature provident of the health and comfort of the people.

Knowing this, does it not appear strange that, after geological proofs have been adduced of the existence of an ample supply of pure and limpid element at no great depth beneath our feet, the efforts of our speculators in it, should be directed either to bringing it to our doors from a distant part of the country, or to pumping it from that receptaculum of every nuisance—the Thames. Boring into the earth, and thus obtaining a never-failing supply has not yet, except in one or two instances, engaged their attention. Private individuals, it is true, who stood in need of better water for their purposes, such as brewers, have sunk shafts to furnish themselves with what the water companies could not : but the latter have neglected this source of providing for their customers.

If we look to the inhabitants of London, there can be no doubt that the quality of the water consumed by them influences their health in a great degree, and when such water is bad that it predisposes to various diseases. Turbid and stagnant pools, exposed to the continual accession of filth and noxious ingredients of every description, are bad reservoirs whence to draw this indispensable ally in our cooking and other operations. The New River, the Thames, and a few ugly-looking ponds in the neighbourhood of Hampstead are almost the only sources from which we draw our supplies. Neither of these is without objection. The New River runs a course of thirty-seven miles ; and, although there is good water at its Ware extremity, it degenerates during its meandering to such a degree, that at Pentonville it is scarcely a shade better than that of the Thames. Nor need we be surprised at this, when we see by the evidence before the Committee of the House of Commons, that it is the receiver-general of all the refuse of the villages by which it flows, and that it has been so for two hundred years ; add to this its slow motion, and that being insufficient in itself to supply the Company's tenants, a portion, estimated at one-third, is drawn from the Thames ; that, as it nears town, the daily bathing in it during the summer months of hundreds of dirty persons of every denomination,—tinkers, sweeps, &c.,—and then its savoury and refreshing character, we presume, must at once be appreciated. The River Lea, from the evidence of Messrs. Wicksteed and Steevens, engineers, is equally objectionable, and even more so, since it is navigated by barges and the Thames tide runs up it.

The ponds or miniature lakes at Hampstead are subject to like objections, with

this addition, that in dry seasons the amount of water supplied is not equal to the demand. This difficulty, however, the Water Company belonging to them has, by a spirited undertaking in the way of boring a well to the depth of above three hundred feet, in a great measure, obviated.

The Thames, last mentioned but not least in villainous quality, it is true, promises to afford an everlasting supply. But the objections which have been noted of the three former apply to it in a ten-fold degree;—drains, water-courses, and stinking ditches, with all their poisonous gases and decompositions, disgorge into and pollute it with all that is insalubrious and disgusting. It is said that the tide comes up and removes the impurities deposited; but we feel convinced, by ocular demonstration and by our gustatory organs, that it is not so. Most people coincide with us in this opinion.

Various schemes founded on as many theories have been suggested to remedy the nuisance alluded to, but all have involved an enormous expenditure of money, and therefore been abandoned. Different points of the Thames have been successively proposed as presenting advantages which afterwards proved fallacious. A company in embryo at the west end has offered to bring water from above Richmond; but it is not only *below* that village that the Thames becomes the depository of all that is vile and nauseous; even up as far as Windsor its qualities are but little better than in London, and the public health would still suffer. Besides, were the water pure at Richmond, it would in its course to town be liable, like the New River, to be deteriorated. Speculators, however, at all times awake, have suggested to meet this evil by forming a covered watercourse. This needs

but little reflection to be rejected; for whoever considers the swarms of vermin and aggregation of pestilent vapours engendered and condensed for want of exhalation in such a contrivance must without hesitation condemn it.

But the desideratum is *pure* water, not water *comparatively* pure. The question is not whether a phial of the fluid taken up at one point contains a few grains less of poisonous ingredients than that taken up at another, but whether it *can* or *cannot* be obtained uncontaminated with *any impurities*. Dr. Lamb, after elaborate analysis, has proved that the Thames water, *wherever* taken up, is full of noxious ingredients. The decision of place, then, upon that river is but one of more or less abomination. Such being the case, the west end speculators could confer no benefit on their customers by deriving their supply higher up our common provincial and metropolitan sewer, when even filtering beds have been tried and found inefficient.

And now, it appears that, although situated in the midst of water, we are in want of a good description of it. What remains but to seek a new source and dig for it? If the surface of the earth will not furnish it in perfection, owing to its exposure to the nuisances already mentioned, it will be wise in us to dive into its bowels, where it has been proved by experiment to exist. If successful in the search, and this admits not of a doubt, then would the fountain of this indispensable aliment spring up close to our homes instead of floundering through miles of uncleanness; and solid advantages, not to be appreciated at a superficial glance, would flow in upon us, and amply reward the toil and expense incurred. Indeed a speculation to bore a well, and erect a steam engine to pump

up its contents into a properly built and guarded reservoir, whence it might be distributed, in every parish, would pay well, and bring a profitable interest on the capital adventured.

It is now well known, that the stratum of clay on which London is situated, although extending to a great depth, has beneath it an inexhaustible source of fresh water, for, hitherto, the supply at one place proved only bounded by the size of the pipe; 100 gallons per minute have been obtained through a pipe of five inches' bore, and in some places a greater quantity. Taking this as a standard, a pipe of 72 inches' diameter would, of itself, afford a supply equal to the consumption of the metropolis, that quantity being calculated in excess, at 38,000,000 gallons per diem. This water, too, would be of a sweeter and better sort than any we obtain now. The success of the well at Hampstead shows that no fear of an insufficient quantity need be apprehended.

We have entered thus far into the subject, deeming it one of vital importance to the public welfare; and in these times, when novel epidemics have appeared among us, one demanding especial consideration. As medical journalists we are observant of whatever causes may produce pernicious effects upon the health of the community, and in adverting to, or commenting upon, them, discharge, in our humble opinion, a bounden duty.

Foreign Medicine.

Menstruation of a Young Woman through the Stomach—Symptomatic Hæmatosis.

A young woman, aged 24, spinster, menstruated at fourteen, the duration each time three days, quantity as ordinary, and this continued with regularity for two years. After that period, and without any assignable cause, the courses became by degrees less in quantity, appeared only once in two or three months, and were accompanied by heat, pain

in the stomach, cephalalgia, and general languor. Remedies of various sorts were tried, especially strong and frequent vomits, but to no purpose; inflammation in the abdomen then supervened, and was successfully combated by antiphlogistics; still the menses decreased in quantity and were retarded in time, and the following symptoms appeared:—extreme pain in the epigastric region, intense cephalalgia, dazzling of the eyes, tinkling in the ears, loss of speech, impossibility of extending the tongue; but memory and intelligence remained, as she afterwards described all she had felt, and every thing which had passed around her. These symptoms were more decided in character and of longer duration, if preceded by very scarce and very irregular menstruation: recourse was then had to bleeding in the arm, on the third trial of which they abated, and the use of speech returned; if, on the contrary, the menstruation lasted several hours, or one whole day, the second bleeding would suffice, but two were always necessary. In this state she continued for two years, was then sent to the Hôpital de la Charité, and attended by M. Fouquier, who, by suitable treatment, and the application of two leeches daily to the vulva, succeeded in restoring the menses to their due quantity and regularity, and herself to perfect health.

Three months subsequently, on being excessively affected by the death of her father, no other cause known, she was attacked by a sanguineous and abundant flow from the vagina, which sometimes lasted a whole month, never less than twenty days, and thus continued for the space of six months, reducing her to the last stage of emaciation and exhaustion. To stop the progress of the hæmorrhagia, the medical attendant administered blighted rye, chalybeate wine, carbonate of iron, sulphate of potass, with the freezing bath. Under this treatment the evacuation was suddenly suspended; but as the period of menstruation approached, the stomach became, and continued, painful to the touch; the abdomen enlarged, and to such a degree during the courses, as to have the appearance of the pregnant state; nausea, heartburn, and irregularity of digestion, accompanied these symptoms, and at length vomiting of blood, with excessive suffering to the stomach; these vomitings occurred once a day, sometimes oftener, but always lasted three days, the exact period of the menstrual discharge. On their cessation, the abdomen diminished to its usual size; local and general symptoms abated, but all returned with the ensuing monthly course, and such was her state, Feb. 3rd, when she entered the hospital.

She is a brunette, black haired, of meagre habit, and nervous sanguine temperament. The abdomen is very painful, especially on pressure; the stomach swelled, *se dessine* under the integuments, and renders a dull sound if struck; pulse small, and *concentis*;

tongue red, rather dry, and pointed. The discharge from the stomach, accompanied by all the usual symptoms and sufferings, returned on the 9th, and lasted through the 11th; the blood was clear, black, liquid, and without clots, rather less, however, in quantity than usual, as a portion of it passed through the intestines, tinging the feces therewith during the three days.

Treatment.—Sulphuric lemonade.

9th. The same, with twenty leeches to the stomach.

13th. Epigastric region always painful; fifteen leeches to the vulva.

14th. Pains in the stomach less violent, but greater heaviness in the head.—Foot-bath.

17th. Same state; gum-water; 15 leeches on the seat.

18th. Violent nervous palpitations during the night.—Antispasmodic drink; balm-water.

And thus the malady must continue its ordinary course until its progress can be checked by revulsions, leeches to the vulva, and every other medicament tending to direct the menses to their natural channel.

On the Employment of Extract of Pulverised Blue Aconitum in Rheumatic Affections.

BY DR. GINTRAC.

The use of blue aconitum has long been recommended in rheumatic and arthritic affections. Murray, in reporting the testimony of several physicians in favour of this medicament, adds his own personal experience of its beneficial effects. Yet the employment of blue aconitum was very limited, owing, doubtless, to the exaggerated praise too often bestowed on remedies which prove, in the end, of no avail, or perhaps to the natural fear of administering a plant reputed poisonous.

I myself was possessed with much doubt and fear on the matter, when I met with the Essays of M. Lombard, Physician to the Civil and Military Hospital at Geneva, on the Efficacy of the Extract of Pulverised Blue Aconitum in Acute Articular Rheumatism. The facts published by that gentleman appeared to me conclusive; they inspired me with confidence, and I resolved to verify them myself. Accordingly I engaged M. Loze to prepare for me a few drachms of the extract used by M. Lombard, which differs from the common, often found by that gentleman inert. It is thus prepared:—The juice of the plant, expressed and submitted to a gentle heat to coagulate the albumen, is evaporated in an alembic, dissolved again in alcohol, filtrated, and again evaporated in a low temperature. Some juice of the plant from the Pyrenees, mixed with a little mucilage to prevent irritation completed the prescribed operation.

The first patient on whom I made trial of the extract was a young man, 24 years of age, who for three years had been subject to rheumatic attacks, and was then suffering most acutely in almost all his joints. The suffering

parts were slightly tumefied, heated, and painful; there was complete vigilance. Neither general nor local bleeding gave much relief; twelve grains of prepared antimony in twelve ounces of water, administered by spoonfuls every two hours, caused at first a slight inclination to vomit. This subsided, and some degree of relief was manifested, of short duration however, and I would not repeat the dose. It was now that I tried the extract; but, not aware of its degree of activity, I gave at first but one grain divided into four pills; no effect; no excitation of the digestive organs—none on the nervous system; then pills of one grain each, gradually, and finally to the amount of eight pills per diem. The effect was complete; in the course of a few days every painful symptom disappeared, his recovery was perfect, and has so continued.

Miss * * *, about 22 years of age, had, in the winter of 1823, an obstinate rheumatic swelling in the right knee, which continued for two months, appeared in the following winter, and again during the last summer, with increased intensity. Bleeding, leeches, cataplasms, emollients, and vapour-baths, various liniments, blisters, revulsions on the digestive tube, sudorifics, and other means, were all employed, and to little purpose; the malady appeared to diminish, tired out as it were. In the autumn she could walk, or rather hobble along; the knee still swelled, leg and foot also, with great stiffness of the joints, and pain throughout the member. In vain were repose, the horizontal position, emollients, and a compressive bandage, tried; they, indeed, reduced the swelling a little, but increased the pain. It was at this period that I tried the extract; the result was prompt, successful, and unexpected. In the course of three days the pain and swelling subsided, the knee returned to its normal state, and she now walks with as much ease as she ever did. No indication of excitation in the digestive organs during the operation of the extract—none in the nervous system.

On a third individual I did not obtain so satisfactory a result. M. M——, 38 years of age, of a sanguine and nervous temperament, was attacked with acute rheumatism in all the articulations of the upper members, back of the head and neck, and thence proceeding to the lower members, accompanied by continued fever. After three bleedings, several applications of leeches, and the trial of antimony, acetate of ammonia, blisters &c., the extract was administered; at first with some advantage, then with none whatever, yet ten grains every four and twenty hours had by degrees been tried. No narcotic or even calming effect resulted; on the contrary, watchfulness with nervous agitation; this latter symptom must be attributed less to the extract than to the great irritability of the patient.

British Hospital Report.

WESTMINSTER HOSPITAL.

Fungus of the Testicle.

HENRY MAUNDY, æt. 25, of the leuco-phlegmatic temperament, a smith, residing at Foot's Cray, in Kent, was admitted into Mark's Ward, Sept. 11th, 1833, under Mr. White.

He says that he has never had either the venereal disease or gonorrhœa, and he attributes the complaint for which he has entered the hospital to a blow he received on the genitals, about three years since, from a wheel, on which he had just fixed a tire, and which he was in the act of raising, with the view of plunging it into the water-trough; he was struck by the part which was heated, but was protected from being burnt by the leathern apron he wore. The pain from the blow he describes as very severe, and lasting several minutes; it then went off, and he did not take any steps to prevent consequences. Tume-faction took place gradually, unattended with pain, and a month elapsed ere he underwent any treatment. He suffered then merely from the sensation of weight in the part; he was bled and had medicine, and the swelling disappeared. Eight months ago, he says he strained himself, and the testicles again began to swell slowly, and without pain; two months since, ulceration of the scrotum commenced, still without suffering, and a fungous growth protruded, which has continued to increase in size, but slowly. Both testicles are apparently affected; the scrotum on each side being ulcerated, but the fungus from the left organ is by far the larger; indeed, there is scarcely any on the right. The fungus is of a dirty-white colour, hard and insensible to the touch, rising, also, on the left, considerably above the level of the adjoining integuments. The scrotum is apparently unaffected except in the immediate neighbourhood of the disease; the cords are healthy.

His general health is unaffected. He has been married two years, but has not had any children. He considers that the generative process is properly performed, on his part at least; and says that he has proved his prowess that way so recently as three or four days previous to his admission.

Does not think that he has derived any advantage from the plan of treatment which has been pursued.

On the 14th he was brought into the theatre, and Mr. White laid open the scrotum on the left side, when he ascertained that the testis was sound. A tent was placed in the wound, and the man sent to bed. Very little irritation followed; but as the fungus continued to increase, the tincture of iodine was applied in the following manner:—strips of lint were applied freely all around to protect the scrotum

and testis, and a piece of lint, folded four times, was then soaked in the tincture, and laid on the fungus. This was at first done once a-day, afterwards twice, and, dating from the 14th of October, three times a-day. Under this treatment the fungus did not increase or diminish, but it became more vascular. It was applied only to the disease of the left side, the right having healed under simple applications.

On the 19th, no real benefit having been derived, he was again brought into the theatre, to have a ligature applied round the diseased parts, but as, on a closer examination, it was feared that the testis would also be enclosed, that intention was abandoned, and Mr. White contented himself with paring away the abnormal growth, until he came to a sensible and vascular part. In doing this, he made a hole or cavity in the centre of it, capable of holding the first phalanx of the index. The fungus, when cut, resembled the tunica albuginea testis in appearance. He was then sent to bed, and the iodine again applied, but without advantage.

On the 7th Nov., the fungus having again risen high above the surface, Mr. White made a minute examination to ascertain the condition of the testicle. On the right side, a body smaller than usual, but equable, and giving a sickening pain on pressure, could be felt. On the contrary, on the left side the testicle could not be felt, and even very great pressure did not cause pain. Mr. White, therefore, expressed his intention to cut down on the diseased structure and remove it. If the testicle was there he would avoid it, but he did not believe there was one. This intention was carried into execution on the 16th, Mr. Guthrie and Sir A. Carlisle having examined the man previously, and given the same opinion. The incision was made as for the operation of castration, carried to the inside of the fungus, and the testis could then be seen at the back and inner part, healthy, but smaller than usual. The fungous growth, therefore, only was removed, and with it that part of the scrotum which was involved in the disease. In order to remove the whole of the disease, it was necessary to shave close upon the cord, in doing which a small abscess was opened, and its parietes were cut away. The parts were then brought together with ligatures, and dressed with dry lint. The operation lasted twenty minutes, and evidently gave extreme pain.

The ligatures were removed on the 19th, and he was doing well; but in a few days some sloughing took place, and pus also collected at the lower part of the scrotum, requiring a counter-opening. The slough soon separated, and he was progressing fast towards a cure, when he became the subject of erysipelas, which affected the parts involved in the operation and the penis. This was combated by the usual means, and on the 31st of December he was dismissed cured.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, March 12th, 1835:—Pelham Aldrich, Stowmarket; William Cass, Liverpool; Esquire Dukes, London; George John Marris Wilson, Greenhithe, Kent; Joseph Chas. Skelton, Bromyard; Daniel Barker, Bransdale, Yorkshire; Lewis Redwood, Boverton, Glamorganshire.

The following are the Medical Estimates for the service of the Navy of the current year:—Provisions and stores of all kinds, including issues from the Naval and Victualling Depots for the several Naval Hospitals and Infirmarys, £16,000, less by £5000 than last year. Medicines, chemicals, and surgical instruments, £4500, more by £300. For the subsistence and cure of seamen in sick quarters and in temporary hospitals, and for other casual accommodation for the sick, and for miscellaneous disbursements for medical service, £2500, less by £500 than last year. The total estimates for this year are £23,000.

APPOINTMENTS.

Naval.—Mr. Alexander Nicol, surgeon, and Mr. James Steel, assistant-surgeon to the Jupiter. Mr. Daniel King, surgeon to the Rattlesnake, vice Magrath. Messrs. John Caldwell, Henry Baker, and William Rogers, assistant-surgeons to the Victory. Mr. H. Fossman, assistant-surgeon to the Alban. Mr. H. D. Shea, assistant-surgeon to the Swallow packet. Mr. J. Scott and Mr. Jack, assistant-surgeons to the San Josef. Mr. Ains with, surgeon and geologist, and Senor Riga, native of Constantinople, apothecary and third interpreter to the Euphrates. Dr. Staunton, Ryl. Artillery, physician and naturalist, and Mr. Staunton, chemist and assistant in natural history to the Tigris, both on the eastern expedition.

Military.—Assistant-Surgeon T. F. Cotton, from the 14th reg., is appointed surgeon of the 12th Foot, vice Orton, deceased. Staff-Assistant-Surgeon H. Drummond, M.D., has been appointed assistant surgeon of the 14th Foot, vice Cotton, promoted to the 12th Foot. Surgeon J. Wyer, from the 74th Foot, has been appointed surgeon to the 10th Foot, vice Waterson, who has received a commutation. Staff Assistant-Surgeon Edw. Hugh Blakeney has been appointed assistant-surgeon of the 67th reg. vice Cumming, promoted in the 74th Foot. Assistant-Surgeon Alexander Cumming, from the 67th Foot, to be surgeon of the 74th Foot, vice Wyer, appointed to the 19th Foot. Hospital Staff—Apothecary Joseph Schembri, from the half-pay, to be apothecary to the forces, vice George Middleton, placed upon half-pay.

General.—Surgeon C. J. O'Hara, Master of the Coombe Lying-In Hospital, Dublin. Dr. Maunsell, Professor of Midwifery at the Royal College of Surgeons, Dublin. Dr. W. R. Mesham, of Woburn, Physician to the General Infirmary, Belfast. Dr. John Abercrombie, First Physician to his Majesty for Scotland, Lord Rector of Marischal College, Aberdeen. Dr. John O'Connell, Medical Attendant to the Rathleague Dispensary, County Leitrim. Mr. Watkins, Surgeon to the Canton female emigrant ship to New South Wales. Dr. D. C. Macneight, of Queen Anne-street, Physician to the Marylebone General Dispensary, Whitebeck-street, Cavendish-square. Mr. Denne, Surgeon to the Kent and Canterbury Hospital.

Resignations.—Dr. Johnson, Professor of Midwifery in the Royal College of Surgeons, Ireland. M'Keever, Master of Coombe Lying-In Hospital, Dublin. Dr. Duncan, Dr. Wilson, and H. Purdon, Jun., Medical Attendants of the Belfast General Dispensary. Mr. —, House Surgeon to the Chichester Infirmary. Mr. Copeman, Apothecary to the Norfolk and Norwich Hospital.

DEATHS.

Mr. Shells, surgeon of the ship *Amelia* Thompson, at Flourat, East Indies. Dr. P. G. O'Connor, of Lauesborough, County Longford. Mr. Dixon, surgeon to the Horsemonger-Lane Gaol. Mr. James Paton, surgeon of the ship *Exmouth*, at Calcutta. In the East Indies, Mr. D. W. Taylor, of the Medical Department. At Newhaven, Scotland, Dr. F. B. Young, of Greensborough, Pennsylvania. Dr. Alexander Rarasay, of Dundee. Dr. Robert M'Grath, of Kilbaron, County Clare. At Montreal, Upper Canada, Mr. M. Mabey, Staff Surgeon to the Forces. Mr. Reginald Orton, surgeon of the 12th Foot. Mr. John Tucker, surgeon, of Bridport, and coroner of the West Division of Bridport. In Bath, Charles Kegan, Esq., formerly of the East India Comp.'s Bengal Medical Establishment. At Charleston, St. Nevis, Mr. Sam. Fitzherbert Bowden, formerly of Bristol, surgeon. Dr. Thomas Williams, of Guildford-street, Russel-square. Mr. J. Ackell, of Bath, surgeon. Dr. D. M. M'Gibbon, late surgeon of the 35th Foot.

BOOKS RECEIVED.

A Synoptical Chart of the Diseases of the Ear. By J. H. CURTIS.

A reprint, on a smaller scale, of the chart formerly published by Mr. Curtis. It will prove of use to those for whom it is designed—the student and the junior practitioner.

LITERARY INTELLIGENCE.

In the press, *Martinet's Manual of Pathology*. Edited by JAMES QUAIN, M.D., Professor of Anatomy and Physiology in the University of London. A new edition, with numerous additions.

CORRESPONDENTS.

Akribes.—The objection is, futile: the society is properly designated the *London Medical Society*, in contra-distinction to the *Westminster Medical Society*. There is not any other association for which it can be mistaken, as all other medical societies in this metropolis are designated either from the name of some celebrated member of our profession, as the *Hunterian* and the *Harveian*, or they bear a more extended appellation, as the *Medical and Chirurgical Society*.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

At the Meath Hospital during the Session of
1834-5.

LECTURE IV.

GENTLEMEN,—I have here the lungs of a patient who died yesterday in the Fever Ward, and to whose case I have frequently directed your attention. They present some pathological phenomena of considerable interest, and I would advise you to examine them carefully after lecture.

The patient, who was advanced in life and of a feeble constitution, had been ill for a week before his admission, with symptoms of dyspnoea, cough, and pain in the left side, which appeared shortly after his recovery from an attack of fever. On examining him the morning after his admission, we found the inferior part of the left lung dull on percussion, the dulness extending much higher up posteriorly than anteriorly. On applying the stethoscope we observed that, over a space about the size of two palms, no sound, morbid or otherwise, could be heard, but above the line which bounded this space there were *crepitating râles* and bronchial respiration. We had, therefore, a two-fold affection of the lung, pleuritis, as indicated by the pain in the side, dulness on percussion, and absence of all sound over a certain portion of the chest; and pneumonia, as indicated by cough and expectoration of viscid sputa, tinged with blood, dulness of sound on percussion, bronchial respiration, and *crepitating râles*. It is unnecessary for me to recapitulate all his symptoms, as I have, while visiting the wards, mentioned them in detail, and I shall merely state, that our examination showed that this man, in the first place, was labouring under pleuritis, and that it was of that kind which is called dry pleurisy, and where there is no tendency to considerable effusion; and, in the next place, that he had pneumonia of the inferior lobe of the left lung, extending up into the middle lobe posteriorly. You will recol-

lect, that, at the time of our examination, I marked on his skin with a pen the extent of the pleuritic inflammation as well as of the pneumonia, and you will find, by examining this lung, that my diagnosis was correct. You will observe the pleura presenting, over its inferior part, laterally and posteriorly, an effusion of lymph, with a very small quantity of sero-purulent fluid; and here is the seat of the pneumonia, which occupied precisely the portion I pointed out and no more.

With respect to treatment it was antiphlogistic, pushed as far as the advanced stage of the disease and the age and debility of the patient permitted. He was leeches and blistered, and this was immediately followed up by the use of calomel and opium, and the application of mercurial ointment over the affected portion of the chest. This treatment appeared to check the disease and stop the progress of disorganisation in the lung, at least it certainly arrested the pleuritis. The pulse became more tranquil, and what encouraged us to entertain some slight hopes was, that the difficulty of breathing subsided and respiration became less frequent, although it was never reduced to anything like the natural standard. I have already told you, that in studying acute and chronic affections of the chest the two chief symptoms to be attended to, are the number of respirations which occur in a minute, and the amount of dyspnoea complained of by the patient. Here, though the respirations sank from forty to thirty, still they were nearly double the natural frequency, and this, coupled with the age and debility of the patient, forbade us to hope for a cure. Though the pulse had become more tranquil, and the bloody expectoration had ceased, though dyspnoea was no longer complained of, and the frequency of respiration had become reduced, still the man's countenance exhibited strong marks of suffering and debility, and the stethoscope showed that the disease still continued, and there was no tendency to resolution in the affected lung. Here the stethoscope was of great value. A person, ignorant of its use, observing the tranquil state of the pulse, the diminution in the frequency of respiration and the cessation of dyspnoea, might be led to

believe that the man was getting better, and to pronounce that the period of convalescence was near. But the stethoscope told us that the hepatisation of the lung had no tendency to resolution, and when we observed, after a week, that it was still undiminished in extent, we were led to form an unfavourable prognosis. We knew that matters could not remain long in this state; we knew that the disorganised lung acted as an irritant tending to keep up disease, and that the man was every moment liable to a fresh attack of inflammation.

In the mean time the patient caught a fresh cold, from being exposed to the thorough air of our too well ventilated wards. This fell on his larynx, producing hoarseness, stridulous breathing, and copious expectoration. When an old person, reduced by some previous disease, catches cold and gets in consequence a sudden and remarkable hoarseness, so that he can only speak in whispers; when, in addition to this, he has cough, stridulous breathing, and copious muco-purulent expectoration, you may be sure that the case is a bad one, and the patient in the most imminent danger. Inflammation of the larynx in children is, you all know, a violent disease, it terminates in an effusion of lymph which, if not prevented, or remedied, by the most prompt and decided measures, too often produces fatal obstruction to the entrance of air and death from asphyxia. In the adult laryngitis does not, except in a very few instances, cause an effusion of lymph; still it is a severe disease, and well calculated to excite alarm. *In the aged* it is accompanied by considerable fever, and, what you would suppose likely to give relief, copious expectoration, evidently derived from the larynx itself,—and yet I do not recollect that I have ever seen a case of this kind that did not terminate fatally. I have very recently visited a case of this description, which occurred in the person of an eminent country practitioner, who had just come up to Dublin. He got an attack of cold, followed by hoarseness, which went on for two or three days without being attended to, until one evening he suddenly became alarmingly ill, and was obliged to send for his friend, Dr. Evanson, who prescribed and called on me the next day. I found him labouring under stridulous breathing, constant laryngeal cough, prostration of strength, and enormous muco-purulent expectoration. His pulse was very rapid, he complained much of oppression of the chest, and died the following night, more with symptoms of exhaustion than of asphyxia.

The symptoms of laryngitis, which arose thus suddenly in our patient, were quickly succeeded by others. On Saturday morning we found him much worse, his countenance was sunk and livid, and his breath had become extremely fœtid. His expectoration also exhibited a very remarkable change, it was greenish, ichorous, and had a most intolerable fœtor. He now began to manifest symptoms of awful prostration, his distress of respiration

became intense, his eyes fixed, his extremities cold, and he expired in about forty hours from the commencement of the attack.

Here, gentlemen, a man, after fever, gets an attack of pleuro-pneumonia, this is relieved to a certain extent by treatment, but the hepatisation remains unresolved. At the end of three weeks he gets an attack of laryngitis; in addition to this gangrene seizes on the diseased lung, and he sinks with great rapidity. Where gangrene attacks the limbs it may creep on slowly, and life may be prolonged for a considerable time, but when it fixes on internal organs its course is rapid, and generally proves fatal in a few days. In the lung, unless the patient's constitution is unimpaired and the disease limited, it will terminate quickly in death, and you have seen that, in this case, it only lasted from Saturday until Monday morning, that is to say about forty hours. After the acute stage of pneumonia had passed away, as denoted by the absence of fever and bloody sputa, and diminution of dyspnoea and frequency of respiration, the case assumes a chronic character, which continues for nearly a fortnight, and then a new order of symptoms appears, manifested by fœtid breath and expectoration, sudden prostration of strength, Hippocratic face, and cold extremities. Those who have watched this case must have been struck with these three remarkable stages, the first stage of inflammation, the succeeding one of chronic disease, and the termination in gangrene. It is not usual to find gangrene of the lung supervening on inflammation which is arrived at the chronic stage, it is most commonly the result of acute inflammation of an intense character, and comes on at a very early period of the disease.

How are we to account for this sudden superposition of gangrene? There was nothing in the nature of the pneumonic inflammation to dispose it to terminate in this way. It had lasted for three weeks, and had arrived at a stage in which inflammation very rarely assumes the gangrenous character. To what, then, are we to attribute it? Partly to the debility of the man's constitution, and partly to an erysipelatous tendency in the air, which is now very prevalent. Except there was something to dispose the lung to gangrenous disease, as an enfeebled habit and a vitiated quality of atmosphere, we could not, under the existing circumstances, have expected such a termination. That this view of the subject is correct, is shown by the simultaneous occurrence of gangrene in another part, which had not been previously diseased, or subject to inflammation, except shortly before the man's death,—I allude to the larynx. If you examine the larynx you will find the mucous membrane at the posterior surface, and where it invests the chordæ vocales, destroyed by gangrenous sloughing. You perceive, then, we had gangrene in the larynx and lung simultaneously. The gangrene of the lung was not therefore attributable to the occurrence of

local inflammation having a tendency to gangrene, but dependent upon a constitutional affection produced by debility and a vitiated state of atmosphere. If this man had chanced to get a wound on any part of his body, I have no doubt but that it would exhibit a gangrenous character, and, in the same way, if he happened to get inflammation of the bowels, it is most probable that this also would have ended in gangrene. I have frequently, in the advanced stage of fever, where the patient is much reduced, and where signs of a morbid condition of the fluids is present, seen gangrene occur simultaneously in various parts of the body. What I wish to impress on you is, that though the inflammation of the lung ended suddenly in gangrene, it was not in consequence of the inflammation having in itself any such tendency, but in consequence of a change produced in the man's constitution by atmospheric influence, and which was favoured by his advanced age and great debility.

The inference to be drawn from the sudden occurrence of gangrene in this case is, that it does not depend merely on violence of inflammation. At one time pathologists were inclined to believe that gangrene was invariably the result of excessive inflammation, or at least of inflammatory action disproportioned to the vitality of the parts attacked, and that it was possible to prevent any inflammation from ending in gangrene by prompt and active treatment. But there are certain states of the constitution which have a tendency to convert every form of inflammation into gangrene, and that wholly independent of the violence of the local inflammatory action. Thus a person reduced by fever, small-pox, or malignant scarlatina, becomes liable to be attacked with gangrene in various parts of the body from the slightest causes. In all parts which are exposed to any degree of pressure you will, under such circumstances, have gangrenous sores formed, and even in parts where no degree of pressure has been exercised sphacelus is not unfrequently produced, as we see in many cases of confluent small-pox, and in the mortification of the pudenda in female children, which sometimes occurs in bad measles. In such instances, gangrene is not preceded by symptoms of inflammatory action, and in the present case it is very probable that no inflammation of the lung, properly so called, preceded the gangrenous affection which terminated life.

Permit me now to direct your attention to the case of a man named T. Kelly, who lies in the upper fever ward, and has been under the care of Mr. Knott. He is at present labouring under an attack of pleuritis and pneumonia, each modifying the other, the pleuritis being here also of that nature which is, by contra-distinction, termed dry. A few particulars in this case demand our notice. In the first place, from looking at this man, and examining his pulse, you would never suppose that he was labouring under a formidable

disease. A careless observer, finding the pulse to be soft, regular, and only seventy-two in a minute, that respiration was tolerably free, and the skin cool, might here very easily overlook the true nature of the disease, and say this man has no fever, no inflammation of any internal organ. Yet a careful examination shows that the right lung and pleura are extensively engaged. In the next place, we find that the pleuro-pneumonia has attacked the upper part of the lung instead of the lower. Pneumonia has a great tendency to attack the lower and posterior parts of the lung; indeed so frequently do we meet it in this situation, that we look upon its occurrence in the upper part of the lung as a rare exception to a general rule. The third point connected with this case is, that though the patient is labouring under pleuritis and pneumonia, his blood does not exhibit the slightest symptom of being affected by this combination of violent inflammations. When drawn from the arm, it separated very imperfectly into crassamentum and serum, and there was no deposition of that buffy coat which has been so often noticed by our ancestors as occurring in pleuritis, and hence termed *crusta pleuritica*. Here, from observing that there was no formation of coagulum, no cupped or buffed appearance in the blood, and that the pulse was soft and regular, some persons would have argued that no inflammation was present; but how false and dangerous such a conclusion would be, any one may convince himself by making a careful stethoscopic examination. The fourth point (which was first observed by Mr. Knott) is, that there is a considerable disproportion in the size of the sides of the chest; the right side measuring better than two inches and a half more than the left. Now there must be some cause for this; and as the man has pleuritis on this side, it would be natural to infer that there is a considerable effusion of fluid in the cavity of the pleura, and that the dilatation of the side is produced by empyema. There are some circumstances, however, in this case which forbid us to adopt such a conclusion. In the first place, this great increase of size in one side of the chest would indicate a very considerable effusion. By empyema, I do not mean the effusion of a quantity of lymph, which does not push back the lung more than a line, but an effusion of fluids of various densities and in large quantity, exercising very considerable pressure on the lung, and pushing it back towards its root. There are two circumstances in this case which should be attended to; first, the man is a labourer, and in such persons the chest, measured across the pectoral muscles, is always found to be on the right side half an inch, and sometimes nearly an inch larger than it is on the left. This is accounted for by the increased development of the muscles of the right side from constant use. In the next place, we find that this man has not only pneumonia and pleuritis, but also a

tendency to superficial inflammation occupying the parietes and integuments of the chest, as indicated by a feeling of pain and soreness in various regions of that side, but particularly at the lower part, where the sound is clear on percussion. Now where the sound is clear on percussion you are aware that no effusion of fluid exists. The fact is, that in addition to pleuritis and pneumonia the man is labouring under pleurodynia with a tendency to inflammation in the superficial parts of the chest. Under these circumstances, we should not be surprised to find some œdema of the parts, and here we have a second cause for the greater measurement of the right side of the chest.

These are the only points connected with this case to which I shall advert at present, except to mention that the treatment was obviously indicated to be antiphlogistic. You might perhaps think that in treating this man it was a matter of indifference whether you had recourse to tartar emetic, either alone, or in combination with nitrate of potash, or to calomel and opium; but you may lay it down as a rule now firmly established, that in cases like this the mercurial plan answers much better than tartar emetic. After bleeding this man, then, we gave him mercury in such doses as to affect his system as rapidly as possible, and we followed up our general means of depletion by the application of leeches, *which in all inflammatory affections of the chest are indicated in proportion to the pain and tenderness of the chest complained of by the patient.* Indeed something similar must guide us in judging how far we are likely to procure relief, *in cases of inflammation of any internal organ, by means of the application of leeches to the surface over the organ affected.* No good is ever obtained by their application, unless tenderness or soreness on pressure be distinctly observable, and the relief obtained is always proportioned to the diminution of this tenderness where it existed. Where it does not exist, the application of leeches only leads to loss of time, we must employ other remedies in such cases.

There is another symptom in this case which might deceive you into the belief that empyema is present; the motions of the right side of the chest are much more limited than those of the left. When you look at him stripped, you perceive an obvious difference between the respiratory motions on each side; the motions of the unaffected are free, and much more extensive than those of the diseased side. Now, generally speaking, this is a symptom most commonly observed in empyema and a few other diseases. It may also exist where there is extensive hepatisation of one lung, for in proportion to the impossibility of air entering the diseased lung, will the motions of the corresponding side of the chest be diminished. How are we to account for it in this man's case? The pneumonia is not extensive enough to cause it, and we have

no evidence of the existence of any effusion into the pleural sac sufficient to explain it. The only way we can account for it is by recollecting that the man has pleurodynia, and as every attempt at dilating the chest gives him pain, he endeavours to controul its motions on that side as much as he possibly can. This is a fact well worthy of notice. It exhibits to us a beautiful provision of nature, which enables a person by an intense discharge of the respiratory function in one lung, to compensate himself for a limited and imperfect performance of it in that half of the chest where it is limited by pain, paralysis, or disorganisation.

As I am on the subject of pneumonia, it may be necessary to make a few remarks on some points connected with it, and first with respect to the expectoration. With the characters of true pneumonic sputa, I suppose you are sufficiently acquainted; you had many opportunities of examining the expectoration of the patient who died of gangrene of the lung at the time he was labouring under acute pneumonia, and while hepatisation was still going on. But I wish to observe, and I beg you will impress this on your minds, that *there may be cases of extensive pneumonia without any expectoration from the commencement of the disease to the period of complete resolution.* A case occurred in this hospital of a young woman, named Mary Nowlan, who had half one lung and the lower third of the other hepatised during a severe attack of pneumonia, and yet it was not accompanied at its commencement by expectoration; there was no expectoration during its continuance, and resolution went on and the lung was restored to its healthy condition without any expectoration. She remained in the hospital for two months, the lung being extensively engaged, and during this time she was carefully watched, but we never could discover anything like sputa from the beginning to the end of the disease. This is a very singular but instructive case. Another fact with regard to expectoration. A man may get an attack of pneumonia, and, in consequence of the rush of blood which accompanies the first access of inflammatory action in the lung, may have at the beginning some bloody expectoration; but after a day or two this subsides, and though the lung is extensively engaged, the patient may not have any expectoration whatever throughout the whole course of the disease up to the period of total resolution. I have seen this occurrence most distinctly marked in a case which I attended with Dr. Marsh. A gentleman who had got an attack of acute pneumonia, had bloody expectoration for the first and second day, but on the third, when I saw him, it had ceased, and all expectoration continued absent for five weeks, at the end of which he completely recovered. He was an intelligent and scientific man, knew well what was the matter with him, and entertained the old notion that all

inflammatory affections of the lungs resolve themselves by expectoration. Hence he looked day and night for its occurrence with considerable anxiety, but not the least sign of sputa appeared. In this case the hepatisation, which was very extensive, became completely resolved in the course of five weeks, and yet it is a singular fact that there was no expectoration whatever from the commencement of resolution to its termination. Hence you may perceive that in pneumonia the sputa may be absent from the beginning to the end of the disease, and that though the hepatisation may be very extensive, still resolution will occur without the slightest expectoration. Again, inflammation may attack a considerable portion of the lung and the patient may have bloody expectoration for the first two or three days, or during the stage of congestion; this may cease altogether, and the patient have no sign of sputa of any description up to the period of complete resolution. These are no doubt rare exceptions to the general law which regulates the course of pneumonic inflammation, in which we have sputa of one kind or other at every period of the disease; but they possess a considerable degree of interest, and it is of some importance to be acquainted with them.

Allow me to repeat here an observation I have already made. The lung becomes attacked by inflammation, this goes on to hepatisation, that is, a certain portion of the pulmonary tissue which had been before pervious, becomes impervious; instead of being a soft elastic crepitating sponge-like body, it becomes solid, inelastic, and very like that organ from which this condition derives its name, the liver. One of the most curious things, the knowledge of which we have arrived at by the discovery of the stethoscope is, that not only small, but even very extensive, portions of the lung may become thus solidified and altered in their texture, so that a return to the normal condition would seem almost impossible, and yet we know that a person may have nearly two-thirds of one lung reduced to this state of solidification, and still become afterwards as healthy as ever. Now if you read Laennec's admirable remarks on pneumonia, and other treatises on the same subject, you will find that the circumstances which indicate the resolution of pneumonia, are sputa of a certain character, and the reappearance of crepitus. I need not repeat here what I suppose you are all aware of, that crepitus commences before hepatisation, ceases on its appearance, and returns again when resolution takes place. The latter kind is what has been termed by Laennec *crepitus redux*. Nature accomplishes the resolution of pneumonia not only by absorption of those particles which the process of morbid action has deposited in the tissue of the lung, but by secretion into the air cells and minute bronchial tubes, and it is the presence of this secretion which gives rise to the crepitus redux. Now the observations which I have made with respect to the total absence of ex-

pectoration in some cases of pneumonia apply here also, for where all sputa are absent, where there is no expectoration from the beginning to the end of the disease, you can have no crepitus redux. This observation I have made in several cases. The fact which I wish to impress on your attention is, that in some cases of pneumonia expectoration may be completely absent; here the crepitus redux is never heard. Thus in the case of Mary Nowlan, resolution went on to the re-establishment of the healthy and normal condition of the lung, without the slightest crepitus being heard. The same thing has been observed in two or three cases by my friend Mr. Dwyer. It is not necessary for the resolution of hepatisation, that there should be increased excretion into the bronchial tubes, during the time nature is employed in absorbing the matter deposited in the lung. In the ordinary way it is removed partly by absorption and partly by excretion into the bronchial tubes. Sometimes, however, interstitial absorption alone seems to be sufficient for this purpose, and the cases I have mentioned prove that it is in the power of nature to remove the morbid product in this way, without calling in the aid of the bronchial tubes. I may, however, remark, that such cases are rare, and that resolution proceeds much more slowly than where free expectoration is present.

Before I conclude, I wish to make a few observations on a case of erysipelas which has recently occurred in our wards. Indeed we have had within the last two days three cases of erysipelas, the disease in two instances attacking patients who lay close to each other. Erysipelas is at present epidemic, and has been so for some time. Its character and mode of treatment have been well described by Mr. M'Dowel in a late paper, published in the *Dublin Medical and Chemical Journal*, which I would recommend you to peruse attentively. It has been observed by Dr. Cusack and others, that when erysipelas prevails as an epidemic we may expect puerperal fever, and scarlatina of a bad and dangerous type. Hence it would appear that the same noxious quality of atmosphere which generates one disease, may give additional malignity to others.

One of these cases of erysipelas occurred in the fever ward under peculiar circumstances. A young woman was admitted some time ago, labouring under spotted fever; she had been many days ill before her admission, and continued for a considerable time in an uncertain state. It is unnecessary for me to enter into any details regarding her treatment, but after the more obvious indications were answered, she was ordered to use the liquor chlorid. sodæ, and became convalescent, or *quam proxime* so. Her tongue began to clean, the abdomen was soft, the bowels natural, the skin cool, and the pulse about eighty. One evening she got fresh symptoms of fever, raved during the night, and next morning, when we visited the wards, we found her pulse accelerated, her

tongue dry, black in the centre, and dusky red at the edges and tip, and, in addition to this, she had some diarrhoea. The nostrils were filled with a semiconcrete mucus, exhaling a most offensive odour, in fact, one could hardly approach her bed without experiencing nausea from its extreme foetor. The inside of the nares was red and swollen, in short, erysipelas was seen occupying the nose, upper part of the face, and forehead. It had first attacked the skin and subcutaneous cellular tissue, producing considerable œdema, and from this it had extended to the mucous membrane of the nose. Erysipelas generally commences in the skin, but sometimes it has its origin in the mucous membrane.

I need not tell you that erysipelas of this œdematous character, accompanied by such a remarkable change in the secretion of the nostrils, and occurring in a person weakened by fever, was to be looked upon as a dangerous disease. I have not time to enter into any further observations on this subject, and will proceed at once to mention our plan of treatment. How did we treat this case? Not by the usual antiphlogistic means, for the patient was greatly debilitated. Bloodletting, leeching, emetics, and purgatives, were here out of the question; however valuable they may be in ordinary cases, we could not use them here without risking the patient's life. You might think that an emetic or a purgative could do very little harm, and might effect much good, but you are to recollect that the girl had nausea, thirst, bowel complaint, and great prostration of strength. What then was to be done? First we applied a blister to the nape of the neck, to act partly on the brain and prevent delirium, and partly on the erysipelatous inflammation of the nose and forehead. How blisters act in this case I do not exactly know, but you are all aware that a blister applied in the neighbourhood of a patch of this kind of œdematous erysipelas, is often followed by very good effects. Whether it is by exciting a new irritation, or by directing the current of the cutaneous circulation to another part, and causing a flow of serum thither, I cannot tell, but blisters certainly do give very considerable relief. So much for external means.

Now with respect to internal, the only one we could give here with any prospect of benefit was the sulphate of quinine. But the patient had nausea, thirst, and diarrhoea, and if you administer quinine by the mouth under such circumstances, you will do more harm than good. I therefore prescribed it in the form of enema, directing five grains of quinine, combined with four of tincture of opium, and two ounces of mucilage of starch, to be thrown up the rectum every fourth hour. Under this treatment the girl began to improve rapidly, the erysipelas faded away, the fever declined, and she is now once more convalescent. I also ordered her nostrils to be repeatedly syringed with warm water and vinegar.

Here, gentlemen, you perceive our treat-

ment has been successful in a case occurring under very unfavourable circumstances. It is a case the study of which will afford you some instruction, particularly if you compare its symptoms, progress, and treatment, with the case of erysipelas which occurred in the strong healthy girl who is lying near, and which we are at present treating on the emetico-cathartic plan.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCUCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXIV.

Dystocia.—Forceps.

GENTLEMEN,—Having completed the subject of eutocia in my last lecture, I now come to describe the various species of *dystocia*, or faulty labour; in doing which I must request you to recollect what I before told you respecting the precise meaning of this word; that it does not mean simply difficult labour, but labour which is faulty, which is incompatible with health. The arrangement which I shall follow is that of Professor Naegele, which is by far the best with which I am acquainted, and which he has still further simplified in a work recently published. He divides *dystocia* into two classes; the first consists of *labours difficult or impossible to be completed by the natural powers*; these may arise 1st, from malposition of the child; 2ndly, from faulty form and size of the child; 3rdly, from faulty state of the parts which belong to the child; 4thly, from a faulty state of the pelvis; 5thly, from a faulty condition of the soft passages; 6thly, from a faulty state of the expelling powers.

The second class consists of *labours which are dangerous for the mother or child, but where the course of labour is not interrupted*; this may depend 1st, on too rapid progress of labour; 2ndly, on prolapsus, &c. of the umbilical cord; or 3rdly, it may arise from other conditions and circumstances which render labour dangerous, as, for instance, convulsions, syncope, dyspnoea, severe and continued vomiting, hæmorrhage, &c.

On finding a want of proportion between the child's head and pelvis, and knowing how much it can be elongated by pressure, it would seem almost natural for a person to try and imitate the expulsive power of the uterus by inventing an instrument like the forceps, by means of which he could grasp the child's head, for they are in fact nothing more than a pair of artificial hands; why they were not

invented till the last century results from people not having been acquainted with the true mechanism of childbirth; if they had known the manner in which the head presents and passes through the pelvis, there is little doubt but that the forceps would have been invented long before; hence, in those times, nothing was used but perforators and sharp hooks for opening the head, or dismembering the child. Where the antero-posterior diameter is less than three inches the compression and elongation of the child's head will be useless, for in such cases a full grown child cannot be born alive; the forceps here are no longer applicable, and the perforator becomes necessary. The forceps consist in the application of a power to the head of the child without injury to it or the mother, it is the simplest of all inventions and the purest imitation of nature. I shall, therefore, speak of the forceps before describing the operation of turning, which is not so simple.

To describe the forceps of the present day in all their varieties would be a most unprofitable task, still, however, they are all formed more or less upon the same original type; they consist of two blades curved so as to fit the child's head, and acting upon each other as a mutual fulcrum at the point where they cross, which is called the lock, their lower extremities being formed into handles. The late Professor Fries, of Münster, supposing that those forceps would have the firmest hold, which coincided exactly to the shape of the head, and touched it in as many points as possible, made a pair of leaden ones, which he bent upon a child's head exactly to the form of it, and then had a pair of steel ones made from them. I know of no forceps which correspond so exactly to the shape of the elongated foetal head, immediately after birth, as those of the late Dr. Hopkins. The greatest distance between the blades should not be less than two and a half inches, because the head can never be compressed through a space narrower than the breadth of the basis cranii, which is two and a half inches.

In Germany, the extremities of the blades are not more than three or four lines asunder; in England they are somewhat more, some especially are very wide at this point: when each curved the blades have a firmer hold, because they act rather like blunt hooks, but their application is rendered much more difficult, whereas if they be too straight, although very easily applied, they require too much pressure to make them hold. The first forceps which were invented had the blades solid, but they were very soon made with fenestræ, which is a great improvement. The forceps of the late Professor Oslander, of Göttingen, are the only ones of modern times which are without fenestræ. Forceps, made with fenestræ, are lighter and hold better, and from allowing the most prominent parts of the skull to pass through, the blades occupy much less room. Until the year 1751 the forceps had

merely the head curvature, or, in other words, what is known by the name of the *straight forceps*; during this and the following year two of the greatest accoucheurs of the age, Levret and Smellie, described forceps which had not only the curvature for the head, but also one to correspond with that curve which is formed by the median line of the superior and inferior apertures of the pelvis. Although Levret published the description of his curved forceps in 1751, viz. a year before Smellie did, yet there is no reason to suppose that Smellie took the idea from Levret, because both had used these curved forceps for some years before they communicated their discovery to the public. Levret certainly possessed them as early as 1747, although not made known till 1751. On the other hand, Smellie expressly mentions that he had contrived these curved forceps "several years ago;" hence, although Dr. Smellie has an equal right to the merit of the invention, there is every reason to suppose that the claim of priority is due to M. Levret. The forceps of these two distinguished men have become as it were the national forceps of their respective countries, those of Smellie being known by the name of the English, those of M. Levret by the name of the French forceps.

After this era in the history of the forceps they received an additional curve by Dr. Johnson in 1769, author of a valuable work on midwifery; besides the head and pelvic curvatures he has made another in the shank of the forceps, with the intention of thus preventing the perinaeum from being too much pressed upon, in other respects they resembled those of his teacher, Dr. Smellie. Since which, new forceps (as they have been called) have been invented without end; in fact, almost every practitioner has considered himself bound to make some little addition or alteration, and has then called them *his* forceps, but they have all been more or less on the same principle as the original ones of Dr. Smellie. I could enumerate some few however which are very peculiar, and for this reason ought to be well known to every accoucheur, such as those of Chapman, Leake, Orme, and Aitken; but for a more detailed account I must refer you to a paper on the History of the Forceps, which I published in the Medical Gazette for January 8, 1831, or to Mulder's *Historia Forcipum*.

The chief points of difference between the English and French forceps are in their handles and lock: the English forceps have the ends set into wood or ivory handles, which have round knob-like extremities for the purpose of giving a firmer hold, as also for tying them together when applied, this however is seldom done; the forceps of Levret terminate in blunt hooks, with the intention that the practitioner should use them as such, where the blunt hook is required, but they can scarcely ever be used for this purpose, and are both awkward and useless. The locks of these two forceps differ as materially as their handles;

in the English forceps the shanks of the blades mutually fit into each other, by means of a deep groove, whereas in the French the blades are joined by a common screw pivot; both have their peculiar advantages, but I know of only one lock which *combines* the advantages of both; the two peculiarities of a good lock are a firm hold and the power of locking and unlocking with perfect facility. As far as respects a firm hold, the common pivot, as used by Levret, answers this object completely, but the difficulty of locking is very great, and the separating the blade is both awkward and inconvenient. On the other hand, the English lock allows us to connect and separate the blades with the utmost readiness and facility, but it does not possess the firmness of a pivot, and is therefore more apt to slip than the other. The lock which I here show you combines the advantages both of the French and English lock, and has, in my opinion, a considerable superiority over either; it was invented by Brüninghausen, of Würzburg. The forceps are designed only for the head of a full grown fœtus, not for a head which exceeds the usual dimensions, as in congenital hydrocephalus, and as a general rule they ought not to be applied as long as the head is above the superior aperture of the pelvis.

The directions for applying the forceps, which have been given by the English authors on this subject, refer solely to where the head occupies the cavity of the pelvis. Mr. Burns says, that the cranial bones should be touching the perinæum. Dr. Hamilton goes even further, and says that the head should be "so far advanced that the soft parts of the woman begin to protrude." There are, however, cases where the chief bulk of the head has not passed the brim, and where, from its large size or a slight contraction of the pelvis, the pains, although active, are not sufficient to press it through. We are not justified in perforating here, and under such circumstances, where the os uteri is dilated, I consider the forceps a much better and safer means of terminating such a labour than the ergot of rye.

The forceps act, 1st, *trahendo ope tractionis*; this is their most important action; 2ndly, when the head is fixed tightly in the pelvis they act as a lever from side to side, exactly as we wriggle a nail out of a piece of wood; 3rdly, they act by compression. From being applied in the transverse or rather somewhat in the oblique diameter of the pelvis, we might suppose naturally that the head would swell out in the contrary direction, which would only increase the tightness with which it is impacted in the pelvis, especially where the antero-posterior diameter is somewhat shorter than usual; this, however, is not the case, for the bones of the head ride over each other, and since the pelvis does not allow the head to swell out in the direction of the antero-posterior diameter, it becomes considerably elongated. From this power, which the child's

head possesses of lengthening itself, we should never be too ready or officious in the use of instruments, for by allowing the head sufficient time it will gradually mould itself to the shape of the passages, and pass by the natural efforts. "No one who has not seen it," says Mr. Burns, "could believe how much the bones of the cranium will overlap each other in a tedious labour; by this means the power of the uterus is very often sufficient to expel a child through a very small pelvis. This needless application of instruments may be excused in some on the supposition of ignorance, while others, from reasonings and principles, may believe it to be proper, but there are others sufficiently unprincipled to have recourse to the forceps or lever whenever the woman is not delivered within a certain number of hours after they are called."

The general indications for the use of the forceps are two,—1st, they are indicated in all labours which are difficult or impossible to complete, either from deficiency in the expelling powers, or from disproportion between the head and pelvis, or from the arm coming down with the head; 2ndly, they are indicated by circumstances or accidental causes, which render labour dangerous for mother or child, and where the danger can only be removed by hastening labour; for instance, in cases of hæmorrhage, convulsions, syncope, great debility, faulty condition of the respiratory organs, danger of suffocation, obstinate vomiting, unusually severe pains in nervous irritable habits, hæmorrhoids which have burst, hernia, retention of urine, congestion of blood to the head, prolapsus of the cord (in certain cases), inflammation of the uterus, &c*.

Baudelocque was indeed right when he said that the forceps were the most useful instrument which had ever been invented. Before proceeding to describe to you the operation of applying the forceps, I will give you a short sketch of their history, because the one is intimately connected with the other; it is not only a source of much useful information, but I think will also prove both interesting and amusing to you. There is no reason to suppose that the ancients were acquainted with instruments which enabled them to extract the head without injury to the child's life. Avicenna, it is true, when speaking of labour being rendered difficult from the size of the child's head, says that if it will not come by the usual means, the forceps must be applied. The question is, what species of instrument these were, and unfortunately the passage in which he refers to them is so short, that it is impossible to form any very correct idea. Albucasis, who lived about the same time, was in the habit of using several species of instruments, of which he has not only furnished us with descriptions but also drawings. Among these we find two species of forceps, the small one called

* Naegele, MS. Lectures.

misdach, the larger one called *almisdach*; they are furnished with teeth, and although they might have served very well to extract the child's head, still its life must always have been sacrificed.

In 1665, an English physician, named Hugh Chamberlen, declared that he possessed the means of delivering a woman without injury to herself or child, in cases where Mauriceau and other celebrated practitioners of that time would be under the necessity of extracting the fœtus by the perforator and sharp hooks; this he took care to make known in the various journals of the day, but kept his discovery a profound secret. Five years afterwards, being implicated in the rebellion in favour of King James II., to whose party he belonged, Dr. Chamberlen was obliged with others to fly the country; he accordingly went to Paris, and began to practise midwifery there. Not having been able to sell his secret in England, he tried the same plan in Paris, and offered it to Louis XIV., for a sum of not less than 1,500*l.* of our present money. For those times this was an enormous sum, and the king was unwilling to give it until he could be certain that the secret was really worth what Chamberlen demanded for it. It chanced at this time that a female fell in labour (*not* at the *Hôtel Dieu*, as Osiander says), whom Mauriceau was unable to deliver; this Chamberlen heard of, and, glad of the opportunity which now presented itself of proving the efficacy of his secret, requested permission to deliver her. I have translated the original case which Mauriceau took at the time, for the particulars of it are very curious, and in some degree show what sort of instrument Chamberlen made use of.

"August 19, 1670, I was called," says Mauriceau, "to see a very diminutive sized female, æt. 38, who had been in labour with her first child for eight days; the waters had escaped on the first day of her feeling poorly, and there was scarcely any dilatation of the os uteri. Things having remained in this condition till the fourth day, my opinion was requested by the midwife, and I advised that she should be bled, and if the result were not sufficiently favourable to justify the expectation of a speedy delivery, I directed that she should take ʒij. of senna infused in water to excite pains which had ceased altogether; this was done the day after, and succeeded in recalling her pains, which dilated the os uteri to its full extent. In spite of all this her labour made no progress, and the child, which presented with the head, remained in the same situation, without being able to enter the passages, which in this woman (who was very diminutive) were so exceedingly narrow, and the bones, which formed it, so compact and so close to each other, and the sacrum curved so strongly inwards, that the day after, when I was called to her assistance, I found it quite impossible to introduce my hand for the pur-

pose of delivering her, although it is a small one, so that, having tried to no purpose, I found it impossible to effect my object, not being able to introduce my hand without considerable force, on account of the narrowness of the bones which form the passage, and, having introduced it, it was so squeezed that I could only move the fingers, nor could I pass it far enough up, so as to introduce the crotchet with safety, and thus extract the child, which to all appearance had been dead for the last four days. Such being the case, I informed the assistants that it was impossible to deliver her, and being themselves convinced of it, they entreated me to extract the child by the Cæsarean operation. This I was unwilling to do, being well aware that death would be the certain result. Shortly after I had left her in this state, without the possibility of giving her any assistance, which I could have done in other cases where there was not such deformity, there came an English practitioner, named Chamberlen, who was at that time in Paris, and who, from father to son, had practised midwifery in London, where he had acquired the highest reputation in this art. Seeing this woman in the state which I have just mentioned, and being informed that I had found it impossible to deliver her, professed to be astonished that I, whom he considered the most able man in the profession at Paris, should not have been able to succeed; nevertheless he promised to deliver her in less than a *demi quart d'heure*, in spite of any difficulties he might meet with. He accordingly set to work, but instead of being a *demi quart d'heure*, he continued for more than three whole hours without ever leaving off to take breath. But having exhausted his strength and resources to no purpose, and finding that the poor woman would probably expire under his hands, he was forced to give it up, and own that it was impossible to deliver her, as I had already asserted. The unfortunate patient died in twenty-four hours after, having suffered the greatest possible violence; and on opening her body after death, and making the Cæsarean section, which I had been so unwilling to perform during her life, I found the child and every thing else situated exactly as I had previously said, and the uterus entirely lacerated, and in many places perforated, by the instruments which this physician had blindly used without the guidance of his hand, which, being as big again as mine, he could not have introduced sufficiently far to preserve the parts uninjured. Nevertheless he had come from England to Paris six months ago, in the hopes of making his fortune, giving out that he was possessed of a secret peculiarly for labours of this sort, and boasting that he could deliver the most hopeless cases in less than a *demi quart d'heure*. He had actually offered his pretended secret to the king's first physician for the consideration of ten thousand crowns, but the result of this unfortunate labour gave him such a distaste to

this country, that he set off for England a few days after, having found that there were men in the art more able than himself. Before setting off for London he called upon me, to compliment me for this work on midwifery, which I had published about two years before, and to inform me that he had never found the operation so difficult as in this case where he had not succeeded, praising me for not having so rashly undertaken what he had done. I received his compliments as I ought, letting him understand that he had been under a great mistake in thinking that it was as easy to deliver women at Paris as he had found it in London. He left for London the next day, taking with him a copy of my work, which he translated and published in 1672, by the translation of which he acquired such a reputation in midwifery that he amassed a fortune of more than 30,000*l.*, which he now possesses, as I have been told by many people who know him, &c."

In the preface to his translation you will find that Chamberlen mentions being possessed of this secret, but excuses himself from divulging it, because he should injure his father and two brothers, who were also in possession of it. He does not speak over favourably of Mauriceau, although he ought to have felt obliged to him, for this translation turned out an exceedingly lucrative publication.

On account of his political principles, he was again compelled to quit this country, and crossing over to Holland, where his fame as an accoucheur had already gone before him, he settled at Amsterdam, where he quickly formed a most extensive practice. He at last succeeded in selling his secret to three Dutch physicians, Cornelius Bokelman, Roger Roonhuysen, and the celebrated anatomist Frederick Ruysch, for a considerable sum, and on the condition that they never divulged it. They therefore continued to practise much in the same way as Chamberlen had done, first fixing the price and then shutting themselves up with the patient, whom they had sworn to secrecy, nor did they seem to be behind him in being determined to make the most of their secret, for they frequently pretended that it was necessary to be employed, where it was not at all required, merely for the purpose of extorting an additional sum from their patient, and were often guilty of the greatest abuse of it. They sold the secret for extraordinary sums of money, frequently making as one of the conditions, that they should receive half the profits, but always under a solemn oath of secrecy.

In the beginning of last century, a professor of anatomy at Ghent, in Flanders, named John Palfyn, a physician of considerable merit, conceiving that he should render his fellow-creatures a great service by discovering this secret and making it known, travelled into Holland with the intention of finding out what it was, if by any means possible. In spite of his most diligent inquiries, it was kept with such secrecy that he was unable to obtain even the smallest

information about it. Being unsuccessful in Holland, but determined to leave no stone unturned by which he might come at the truth, he passed over into England, and, at last, although he had not succeeded in obtaining a sight of it, yet, from the result of his extensive inquiries, he fancied that he had formed a tolerably correct idea of it, and made two blades like a pair of spoons or hollow hands, and called them his artificial hands. He tried them on the dead body and they succeeded. Contrary to the mean practice of Chamberlen and the Dutch physicians, he immediately took his discovery to Paris, whither he was going for the purpose of publishing his work on anatomy, and presented it to the Academy.

This was one, although not the earliest, origin of the French and English forceps. It is not improbable that Palfyn was considerably assisted in his idea of the forceps by a blunt hook which Mauriceau was in the habit of using to extract the head, in cases where it had been separated from the body and left in the uterus, merely with the difference that instead of pressing his fingers against the opposite side of the head, as Mauriceau did, he used a second blade, similar to the first, for that purpose. These blades did not cross each other, as the present forceps do, but their handles were either held one in each hand, or merely brought together and then tied. Moreover, when we consider that Palfyn had published an anatomical description of the female organs of generation, with plates, in 1708, which was intended as a continuation to Mauriceau's work, there can be hardly any doubt but that the knowledge of Mauriceau's blunt hook must have assisted him considerably in the discovery of his *tire tête*, as it was then called. Palfyn's instrument was somewhat changed by the celebrated surgeon Heister, but Petit was the first who described a pair of forceps, the blades of which crossed and were united by a pivot. These, again, were improved by Dusée, and communicated by him to Dr. Alexander Butler, of Edinburgh, who published them in the *Medical Essays and Observations*, 1733. The blades of these instruments, however, were solid; still although nothing else had been used in Paris but them, forceps with fenestræ had already been used in England. Dr. Johnson, in his *System of Midwifery* (1769), says, "I have a pair of forceps which did belong to a Mr. Drinkwater (late surgeon and man-midwife at Brentford) who began to practise in 1668, and died in 1728. The form and size of this pair agree with those of Chapman and Giffard, save only that the hooks of the handles are turned outwards." Whether Drinkwater obtained his forceps from the Chamberlens or invented them himself, it is difficult to say; certain it is, that Giffard had used his extractor, which so resembles these forceps, two years before Drinkwater's death. Chapman improved this instrument considerably, and thus it came into the hands of Dr. Smellie. According to him, these forceps were

adopted by the French, and were known in Paris by the name of Chapman's forceps, and when we come to examine Gregoire's forceps, which are the straight ones of his pupil Levret, we find them almost exactly similar to those of Chapman. On what authority Dr. Smellie asserts that they were originally used by the Chamberlens, I know not.

Let us now, gentlemen, return to Holland, and learn the fate of Chamberlen's secret. As Roonhuysen and his family had enjoyed the greatest practice in Amsterdam, it was generally called the Roonhuysen secret; it was known only to those who had paid a very heavy sum for being made acquainted with it, and this was always under a strict oath of secrecy. Thus for more than half a century had the Dutch practitioners the meanness and cruelty to keep it entirely in their own hands. At last it became such a necessary acquirement for those who practised midwifery, that on Jan. 31, 1746, a law was passed that no person should be deemed fit to practise midwifery in Amsterdam, who was not duly acquainted with the Roonhuysen secret. This was only to be obtained at a considerable expense, and now that this new law existed, the professors (who were all members of the Apothecaries' Guild or Corporation) were enabled to fix just what price they liked. At this time a practitioner named Rathlauw settled at Amsterdam and passed his examinations before the medical college; no fault could be found, but they objected to him on the score of his not being possessed of the Roonhuysen secret, which he either did not choose, or could not afford, to purchase. To obviate this, his friend, Cornelius Hendrik Velsen, of the Hague, sent him, in 1747, an instrument which he had received from Van der Swamm, a pupil of Roonhuysen. Rathlauw published a drawing and description of it, upon which the accoucheurs of Amsterdam, viz. Bökelman, a son or grandson of the original purchaser, and four others who were in possession of the secret, declared that he had not the real secret of Roonhuysen, but merely a speculum uteri, which was a useless and dangerous instrument. Rathlauw, however, answered and silenced them. It was in 1753 that two Dutch physicians, Jacob de Visscher and Hugo Van de Poll, actuated by the benevolent motive of making this important secret generally known, after considerable expense and trouble, succeeded in purchasing what was generally said to be the Roonhuysen secret, of Gertrude de Bruin, the daughter of a deceased practitioner, who had been known to have received it from Roonhuysen himself; it proved to be this flat iron, slightly curved at the extremities, which I now show you, and which has been commonly, although, in my opinion, erroneously, called the Roonhuysen lever. It is a remarkable fact, that wherever the secret has been described as in Roonhuysen's possession, it has been always mentioned as a double instrument, nor have we any proof whatever that Roon-

huysen ever used a lever of this sort. From the best authorities extant, the lever seems to have been invented some time afterwards, for there is every reason to know that the flat bar of iron which is before you, was invented by Plaatman, who, together with the above mentioned de Bruin, purchased the secret of Roonhuysen. The subject is highly interesting, and you will do well, at a leisure hour, to peruse two short papers upon this subject which I published in the *Medical Gazette* for Jan. 8, 1831, and in the *Edinburgh Medical and Surgical Journal*, for October, 1833. In the latter you will also find a description and delineation of the instruments which were found at Woodham Mortimer Hall, in Essex, a house which once belonged to the Chamberlen family. It is impossible for me, gentlemen, to enter into all these particulars during a lecture, because our time will not permit. You will find in the other paper, which was published in the *Gazette*, how Chapman's forceps, having undergone certain alterations, became those of Smellie, who also added the pelvic curvature, and that thus they have come down into our hands. So secret had the Dutch practitioners kept the knowledge of these instruments, that even in 1725 Smellie did not know of the forceps. Some authors even doubted whether Chamberlen did use an iron instrument of this sort; thus Exton, in his work on midwifery which was published in 1751, considers that it must have been some easy method of turning, and Groenwelt, who afterwards settled in England under the name of Greenfield, in his essay, "De tuto Cantharidum Usu, &c." supposes that it was a species of speculum uteri.

In Germany the forceps were not generally known until about 1760, when they were introduced into general use by G. W. Stein, one of the most distinguished pupils of Levret. Hence the German schools of midwifery were little more than a translation of the French schools, and continued so with little change until 1789, when the celebrated Boer of Vienna became one of the first converts to the use of the English forceps. In Copenhagen the forceps seem to have been used at a much earlier period; an accoucheur, named Bing, had used forceps some years before 1750, at which time a description of them was published by Johann Gottfried Jancké; they are the straight forceps without fenestræ, connected by means of a screw pivot, the handles forming blunt hooks, but the chief peculiarity in them is that by means of a very simple contrivance the handles can be separated from the blades, for the greater convenience of application and of carrying in the pocket; it is much superior to a similar invention of modern times.

The forceps of Matthias Saxtorph, of Copenhagen, so well known for his celebrated inaugural essay on the Mechanism of Childbirth, in 1771, had handles somewhat similar to those of Bing, only instead of taking off they folded back by means of a hinge; this species of

handle has been since used by Professor Hamilton of Edinburgh. In other respect Saxtorph's forceps resembled those of Smellie, both in the blades, lock, and handles, except that the whole instrument was upon a larger scale.

—

**CASE OF FISTULA IN PERINÆO OF
LONG STANDING TREATED BY THE
ACTUAL CAUTERY, WITH SUCCESS.**

BY A. C. HUTCHINSON, ESQ., F.R.S.

—

It is with pleasure that we insert the following interesting case, coming from such an able surgeon as Mr. A. C. Hutchinson. We may also remark, that we witnessed the case in question, and have of late seen the individual, who is, at the present time, in the enjoyment of excellent health.—EDS.

Early in December, says this gentleman, my neighbour, Mr. Devonald, called me in to the case of James Wilson, aged forty-nine, residing at 29, Wells-street, Oxford-street, who had laboured under fistula in perinæo for about fifteen years; and during the last twelve months was wholly confined to his bed. He had not passed any urine through the natural meatus for upwards of one year; and, to relieve himself, had been under the necessity of sitting upon a convenience for the greater number of these years, until he had become bed-ridden; and I can never forget the smell that met me when the room-door in which he lay was opened—no stable was half so bad. We found him lying upon a rotten mattress soaking in his own urine, which was unconsciously dripping through *thirteen or fourteen* fistulous openings in the perinæum round the anus, through various parts of the scrotum, and two were situated as high as the pubes above the dorsum of the penis, one on each side; while a basin was on the floor immediately under him for the reception of the urine that filtered through the bed. The case, indeed, seemed hopeless, but, notwithstanding which, and his refusal to be sent to a hospital, upon his consenting to submit to whatever treatment might be thought proper, I took him under my own care.

Upon the second attempt I succeeded in forcing a small tube, with the bulb at the end filed off, through the closed part of the urethra in the *corona glandis*, and which we kept pervious by leaving a portion of bougie in the part properly secured. We proceeded in this way until the 16th of December, when I was enabled to pass an ordinary-sized silver catheter into the bladder, which we retained there for a day or two, and then replaced it with one of elastic gum. After confining the patient as much as we could to low diet, from the period I first saw him, and purging him well on the 21st of December, on the following morning he was placed in the same position as for the lateral operation for stone, without being bound; and the elastic gum catheter

being again replaced by one of silver of larger size (No. 11), and, standing on his left side, I cut down with a scalpel, through the bulb, into the membranous part of the urethra, commencing the incision by the side of the anus, and carrying it forwards upon the catheter upwards of two inches, assisted by my friend Dr. Richardson, the Arctic traveller, and Mr. Devonald, who held the catheter. In this space no less than five fistulous openings were exposed, and four of them freely laid open by means of a director and bistoury. The external or skin apertures of two of these, through which the urine passed direct from the urethra, were three inches from the nearest part of the first or urethral incision, and the whole of these fistulous channels were hard cartilaginous tubes, from one end to the other.

Judging that enough had been accomplished at one time, we deferred doing more until some progress should be made in the absorption of the cartilaginous channels, and in the filling up of the incisions we had made. Forty drops of laudanum were administered. A gum elastic catheter, sufficiently large to prevent the passage of urine between its sides and the mucous membrane of the urethra, was introduced into the bladder. The bladder was emptied at pleasure by the removal of a small wooden peg fitted to the end of the catheter, and this instrument was secured in its place by proper bandages and tapes, being removed about every third day for the purpose of clearing it of mucous and sabulous matter, and then replaced with a fresh one.

The patient passed a tolerable night but in the morning he was feverish, with a full pulse and flushed countenance. He was bled, therefore, to twenty ounces; a purgative was administered, followed by fever mixture; by which means, and the constant application of warm fomentations to the perinæum, the establishment of suppuration in the wounds was accomplished, and with it these unfavourable symptoms disappeared, which for a period of forty-eight hours were rather alarming.

After a few days the remaining fistulous opening was divided; red precipitate with burnt alum was sprinkled along each of the cartilaginous channels every other day for about a fortnight, but without the slightest impression being made. With the same view caustic and nitric acid were applied, but with the same results.

It may here be thought proper to mention, that towards the commencement of the incision, namely, at the membranous part of the urethra, and about half an inch anterior to the bulb, there was but little cartilaginous matter; up to this last point, therefore, the catheter was shortly covered with a healthy granulating surface, in which space, however, but one fistulous opening originated.

As the patient's general health was now good, it became necessary to adopt some new plan of local treatment with regard to the removal of the several tracts of cartilaginous

matter. Every sort of treatment, local and general, that could be thought of, hitherto failed in destroying them, as has just been stated. Some cauterising irons were made, under Mr. Devonald's directions, of certain conical shapes, to suit the channels they were intended to traverse, and which I thought preferable to dissecting them out. These irons were first used about five weeks after the operation of the knife, and repeated every fourth day, sometimes at a white heat, but more frequently the heat was only red, and passed rapidly along the channels, carefully avoiding the external skin; after about three applications of the actual cautery there no longer remained any cartilaginous matter; and the rapidity with which the parts filled up by healthy granulations was most remarkable.

In about ten days after the first application of the cautery I carried the incision fully two inches further forward upon the catheter into a fresh portion of the urethra, cutting upon the *raphe* through the *scrotum*, drawn up over the *penis*. And here, again, we met with the same cartilaginous matter lining the fistulæ, arising from the last portion of the exposed urethra, as from the former, but which gradually lessened in induration as the incision approached the *corona glandis*. Six of these fistulæ, arising from this newly exposed portion of the urethra, were now brought into view, but four only were laid open as before with the bistoury, and the cautery was applied once to each. The remaining two opening upon the pubis could not, with any safety to the patient, be divided, and instead small setons of silk thread were passed through each. These two, we were informed, were the last that had shown themselves, and through which only a few drops of urine used occasionally to trickle when lying inclined to one side or the other.

The same success attended the use of the cautery to the four as on the former occasion; but, before we could entirely close this part of the incision, three smaller fistulæ were likewise to be divided; when, after this, and the diminution of the seton by the daily withdrawing of a thread, the parts were at last completely cicatrised and consolidated.

During all the various operations not one blood-vessel requiring a ligature was divided. The catheter, in this case, was retained for the first seven weeks night and day, after which it was only introduced at bedtime, and well secured for the night; and, at the end of a little more than three months, Wilson was pronounced cured, voiding his urine in as full a stream as he had ever done, and without the slightest inconvenience of any kind resulting either from his previous disease or from the various operations we had recourse to. He continued, however, to come to my house once or twice a-month for some time, for the purpose of having a bougie passed to satisfy me that the urethra had no tendency to contract;

and on inquiry, a few months ago, I was informed he continued well.

To the young surgeon this case presents some practical points requiring particular attention. The first is, that where the disease may be of long standing, and the *fistulæ* numerous, the operation should be done in detail, and not at once; for had we done so in Wilson's case, the febrile attack was so severe that we should have lost our patient. The second is, that the catheter should completely fill the urethra, even to stretching, to prevent any urine passing by its side, and to be constantly kept in the bladder until the cure be at least half completed, when it may be removed during the day, charging the patient not to attempt emptying his bladder without the instrument. Thirdly and lastly,—the extraordinary good effects of the actual cautery in cartilaginous fistulæ were very apparent in this case; without it we must either have lost our patient, or the operation be rendered completely abortive. In all my practice I never witnessed more immediately marked beneficial effects from any remedy in any disease, excepting only after incisions in erysipelatous inflammation. I have also, of late years, found the occasional application of the cautery very successful in arresting the destructive progress of lupus, and other kinds of phagedænic ulcers, and in stopping hæmorrhage where circumstances preclude the convenient application of a ligature to the bleeding vessel. The use of this powerful remedy is well known on the Continent, where it appears never to have been laid aside, as in England; but the practice of our continental brethren is now become well known and appreciated in this country.—*Edin. Med. and Surg. Journal.*

SUPPLY OF WATER IN INDIA.

From an article, written by the Editor, in the 2nd number of the *India Journal of Medical Science*, it would appear that Calcutta is as fully provided with bad water for culinary and other uses, even *pro potu ordinario*, to use a medical phrase, as our far-famed metropolis. That the City of Palaces should thus suffer, and that, too, at a season and in a climate where there is certainly no superfluity of moisture in the human system, is monstrous, and calls aloud for remedy. Our rich drink their wine, and care not for the impurity of the water; our poor discuss their spirits, and reject the weaker, and scarcely less impure, fluid; but the unfortunate Indian cannot procure either of these liquors, and must content himself with the foul and brackish water of the tanks or of the river. But we will allow our brethren of the Indian Medical Press to speak for themselves.

“The state of the weather during the greater part of last month, and more especially between the 8th and 25th, was oppressive to a degree that we scarcely recollect anything to equal it.

The usual north-west winds during this scorching interval were wanting, and the nights were overpoweringly sultry. In the morning the thermometer generally stood at 92°, and in the middle of the day at 96°, and even higher in some houses. Although, generally speaking, we are disposed to consider the warm weather as, on the whole, the most healthy in the year, yet when the heat becomes, as it did during this season, extreme, it must be expected that a great deal of sickness will be the result, more especially among those who are much exposed to its unmitigated power. Even to persons who remained all day in the house the sensation of heat was intense; what, then, must it have been to those whose occupations required them to be much in the open air! All classes, indeed, at such a juncture suffer from excessive thirst. To allay this, the mass of inhabitants look to the river and the tanks. The water in several of the latter, however, has been exhausted in watering the roads; and the river, and the remaining tanks, generally become brackish during the hottest part of the season. The water in the Lalldingy, for instance, is usually pure, soft, and sweet, but of late it became so disagreeable, that most persons who could procure water elsewhere gave up drinking it, and preferred sending for some even as far as Allipore. We have tried the experiment of filtering and purifying the Lalldingy and river water, but without the effect of rendering it palatable. It is all very well, however, for those who can mix some qualifying ingredient with indifferent water, or who have some other means of quenching thirst; but it is very different with the poor—and with the natives generally, rich or poor. They have neither tea, nor beer, nor soda-water, nor brandy and water; they must trust to the brackish and foully surcharged water of the river, or muddy and half evaporated tanks reeking with fish. The English, perhaps of all people, are most indifferent respecting a supply of that vital element, water; their own country abounding with the purest water, they apparently do not consider that it is very much the reverse in other places. We have now been in possession of India a sufficient length of time to make us blush to think how little has been done towards the supply and conveyance of water for the purposes of comfort and existence. What would not the Romans have done in the same space of time! What is the remedy for this? To us it seems that the proper remedy, in the first instance, is, to draw water from the river *only* for sprinkling the streets—but it would be proper, for meeting the wants of the city in an efficient manner, that one or more steam-engines, like that at Chandpaul Ghaut, should be erected; this would leave the tanks with their proper supply. But, in addition to this, the earth ought to be bored for springs, which would afford a permanent supply of pure and fresh water that would not be affected by the state of the weather. An experiment of boring for spring water has been going on

for some time in the Fort; but there is no valid reason why one or more such should not be tried in other spots that may, for aught we know, be more favourable for the purpose. Two or three artesian springs in Calcutta would be a source of immense convenience and blessing to the poor, thousands of whom perish annually, in the hot weather, from the badness of the water."

Reviews.

Consumption, Why so Fatal? What are the Means by which it can be Prevented in those Predisposed to, and its Progress Arrested in those already Affected with it? The above Queries solved in a manner intelligible to every Reader, Experience and Common Sense furnishing the Solutions.
By JOHN TYRRELL. London: Renshaw. 1835.

THAT a non-medical man should write a book on phthisis pulmonalis certainly savours of presumption, seeing that all the talent of the profession has been expended upon the subject almost in vain; yet, on the contrary, it may not be impossible that, since the profession has failed, an amateur, unworped, as we should imagine, by physiological subtleties and scholastic dogmas, may meet with better success.

Let us see what the book contains, what are the topics discussed, what the arguments advanced, and the conclusions which are arrived at. The professed object of the work is to show that consumption is not curable, and why its fatality? The first position is proved by the concurrent experience of all ages and all nations, save one or two arrogant individuals, and a few old women, who impotently affirm its curability. The writer of this volume has afforded himself and his readers a copious illustration of opinions in the writings of almost every writer on consumption. There is, moreover, a strange medley, for besides the opinions of Hippocrates we have a short account of his birth (as well as his contemporaries), and a statement of his talents and renown. Not one of his doctrines, however, are relevant to the object for which they were adduced, mere isolated aphorisms, common assertions without proofs, or even the attempt at proofs. Celsus comes next under contribution. Celsus was, no doubt, a great man, and so was Julius Cæsar, but neither of them knew any thing of consumption.

"For phthisis Celsus advises change of air." He recommends milk diet, and "an ulcer is to be made with a red hot iron under the chin, another under the throat, in two places on each breast, likewise at the extremities of the blade-bones, which wounds are to be kept open till the termination of the cough, &c." "The principal things are diet, gestation, sailing, and gruel. He who begins to be a little better should increase his exercise, friction, and food,

then rub himself holding his breath." Thus we see that Celsus did, however, know as much as even we learned physicians of the nineteenth century how to treat consumption. His knowledge of the pathology of the disease was scanty, nay he knew nothing respecting its nature. Why the author before us should have quoted Celsus on consumption is to us paradoxical. Then comes another bright luminary, "Galen," who treated consumption as we of the present day do; some severe forms of the malady he pronounces very shrewdly to be incurable, certain mild ones to be curable. The character of this triumvirate, by Bacon, whom our author has adduced for what purpose we are unable to opine, we shall give to our readers:—

"Galen," he said, "was a man of very narrow mind, a deserter of experience, an idle caviller. This is the man that would screen the ignorance and sloth of physicians from their deserved reproach, and preserve them unattacked, whilst himself most feebly and unequally pretends to perfect their art, and fill up their office;—this is the man that pronounced certain diseases incurable, taking away all glimmering of hope, and leaving no room for future industry;—this is the man who, upon every occasion, maliciously curbed the human power, and endeavoured to surround and protect ignorance with eternal despair.

"Let Hippocrates be next called to the bar, whom we arraign as a creature patched up of antiquity, and a retailer of other men's knowledge; under whose authority both Galen and Paracelsus ridiculously endeavour to shelter themselves, like asses under a tree. To do him justice, he seems to have his eyes at first fixed upon experience; but then they are fixed indeed—stupid and immovable, without ranging and searching for noble, manly, and full views.

"Celsus comes nearly up to the views of Hippocrates, which are not so faulty as they are useless; but he shews himself a mere practised sophister, and a better modeller of history than his master. He is, however, for checking science, from moral and civil considerations."

Mr. Tyrrell takes a cursory glance at the various opinions on each question, of cause? pathology? and treatment? and he arrives at the following conclusions, which we shall extract at large:—

"That it depends upon the softening of tubercles.

"That debility of the lungs always precedes their production.

"That the debility necessary to their production is excited and increased by every species of pulmonic disease, varying with its extent and duration, from common catarrh to acute pneumonia.

"That the power of resisting the exciting cause of tubercles depends upon the strength of the constitution and the previous habits of the individual.

"That tubercles are imperfectly organised.

"That so long as they are protected from inflammation and suppuration, they will not, *per se*, prove fatal in one instance perhaps out of five hundred.

"That the same means which prevent the inflammation of tubercles will tend to prevent their increase.

"That the suppuration of tubercles is so far connected with the existence of expectoration, that the former *never* occurs without the latter.

"That the congestion *always existing* in the lungs during the softening of tubercles, should, in every case, be the first object to remove.

"That the necessity for its removal and the means are the same in either case—whether we consider the tubercles vascular or inorganic—whether as vascular bodies they suppurate, or as inorganic they are softened.

"That deep inspirations and strong expirations of cool air can, like vomiting, reduce this congestion, without exciting a similar exhausting languor and lethargy.

"That, provided hæmoptysis does not exist, this inhalation of cool air can *never* be injurious in any pulmonic disease.

"That the same process of inhalation can be serviceable to persons in comparative health.

"That such inhalation, like vomiting, stimulates all the secretions concerned in chyli-fication, and contributes to remove dyspeptic symptoms, by reducing any existing congestion in the liver, spleen, or other abdominal viscera."

Now after the remarks we have made, and the extracts we have given, our readers may be safely left to form their own opinions on the value of this work on consumption by an amateur writer. We are not in the habit of condemning a production because it has a few faults, nor of giving it unqualified approbation because it may possess a few beauties. A subject of such vast importance, however, as consumption should not be treated upon, except by one who is thoroughly versed in all the varied departments of medical science; to elucidate it accurately, that it may be acceptable to science and aid us in our therapeutic measures, requires the most profound logician, one who, like the mathematician, takes nothing for granted but what can be substantiated by an immense series of facts, or supported by the closest analogies. The ancients indulged in hypotheses on consumption, as they frequently did on every other subject, and they produced doctrines which advanced science and increased experience have totally exploded. The immortal discovery of Laennec, the patient observation of Bayle, the great experience of Louis, not to omit many of our own countrymen, have taught us to recognise consumption during life, to distinguish its stages and its progress to an almost unerring certainty. But they tell us the lamentable story of its *incurability*. When

St. John Long said he could cure consumption, the British profession reviled and mocked at him as a vile impostor. Facts at the present collected warrant us to affirm with boldness, and yet we trust with that modesty which should ever be the companion of science, that no remedy has yet been discovered for consumption. Dr. Mossman said that digitalis would cure the first stage of consumption, would as certainly cure the second, and as certainly alleviate the third. Experience denies the statement. What medicine has not been tried for its removal, what means have not been devised? the mind has tortured itself to discover a remedy, but all to no purpose. It is a melancholy reflection, but a fact.

We do not think the author of this work has added anything to our stock of knowledge on this complaint. He has made a fair compilation, which does him much credit, but we do not think he has accomplished the objects of his laudable undertaking, yet the book will no doubt be read by the public.

A Manual of Experiments illustrative of Chemical Science, systematically arranged.
By JOHN MURRAY, F.S.A., F.L.S., &c. &c.
London: Henry Renshaw. Pp. 156.

Chemistry is a science of demonstration; it requires, in the individual who cultivates it successfully, almost unremitting toil, and an observation unwearied. Speculation has done little in advancing its progress; and the student who wishes to acquire its treasures must labour for them himself, and the laboratory must be the scene of his study.

The little work before us has arrived at the fourth edition in a very short space of time. At this circumstance we feel no surprise, when we remember that it is small in compass, and the production of one of the first chemical experimenters, and one of the first scientific men, of the age. The following is the table of contents:—"Remarks on the New Nomenclature—Theory of Definite Proportions—Definition of Gases, and Method of preparing them—Experiments illustrative of Chemical Science systematically arranged—Tests for the Detection of Metallic Poisons—Mineral Waters and their Contents—Nomenclature—Vocabulary of Technical Terms—Tests or Re-agents required in Chemical Analysis—Some Apparatus requisite—Descriptive List of some particular Apparatus."

At page 21 the author seems to doubt the validity of Sir Humphrey Davy's theory on the liquefaction of carbonic acid gas by the elastic force of the vapour of sulphuric æther, combined with the application of heat. In support of his objection he advances the subsequent remarks:

"I am not without considerable scepticism on this question. Some years ago Sir David Brewster showed me an experiment in conjunction with the singular expansion of the fluids in crystals, then a recent discovery of

his, which, by the approach of a heated wire, completely and instantly filled their respective cavities. The experiment referred to consisted in introducing into the fire a tube, *partially* supplied with sulphuric æther, when the liquid expanded and entirely filled the tube. It was necessary to screen the face, from an accidental explosion, by sheets of talc, which permitted the experiment to be seen, and yet formed a defence against possible injury. The peculiar character of the vapour of æther, referred to as my discovery, being extremely elastic, yet capable of condensation into a liquid form, would render the liquefaction of the carbonic acid gas as a phenomenon extremely equivocal in this particular instance."

In the next page, when discussing the application of highly compressed gases as mechanical agents, he states that, with reference to liquid carbonic acid,—“Vessels sufficiently powerful to resist its tremendous power have not, however, yet been found, and are likely to interpose a barrier for some time to its practical employment; besides, the liquid gas is found to exude even through metallic cylinders;” he then introduces a good cautionary remark on the dangers which are liable to accrue in their formation.

“The preparation of these liquid gases is so pregnant with danger, that their introduction and exhibition in a lecture-room are not *warrantable under any circumstances*. Whatever risk the operator may personally choose to run in his laboratory, he incurs a frightful responsibility in daring to bring the lives of his auditors into jeopardy. It is hoped that the recent melancholy death of Mr. Barry will operate as a salutary caution and warning against introducing such dangerous and formidable materials. In braving the dangers of the laboratory I will yield to none; but I should tremble to peril the lives of others.”

The following is a pretty illustration of the “Indestructibility of Matter.”

“Pour a solution of caustic potassa into a vessel containing carbonic acid gas, and cover it immediately with a wet bladder, then shake it, and the bladder will become hollow. Add a little muriatic acid, and the carbonic acid will refill the vessel.”

By this, of course, the author does not mean that any portion of matter has been annihilated, but there is an apparent indestructibility of matter from the absorption of the carbonic acid by the potassa, which, on the addition of the muriatic acid, the two former elements are again disunited.

It will suffice for us to state, that each topic enumerated in the contents is treated in a concise yet lucid manner. The majority of the important facts in chemistry are brought under the notice of the reader, and the data upon which these facts are founded, and the means of verifying their accuracy by the most simple experiments, are shown. We may be allowed to give the following facts which the author enumerates respecting carbonic acid gas:—

Carbonic Acid Gas.

"I. If a taper be inflamed and introduced into the gas it is extinguished.

"*Ration.*—This proves its negation in combustion.

"II. If we breathe, by means of a tube, through *lime-water*, it will become turbid or cloudy.

"*Ration.*—Carbonate of lime is formed. The carbonic acid evolved from the lungs combines with the lime, and forms an insoluble carbonate of lime.

"III. Hence, if a little *lime-water* be poured into a vessel containing carbonic acid gas, it becomes milky.

"*Ration.*—Carbonate of lime is formed, as in the previous example, evincing at once a distinction between azote and carbonic acid gas.

"IV. This gas may be poured over a candle, when it will be extinguished. It may also be *laved* from one vessel to another; transferred or emptied by stopcocks, and poured through a funnel, or pumped out.

"*Ration.*—These interesting facts show its superior specific gravity, and the various modes by which it may be got rid of, as being pumped from a well, mine, &c., or emptied by the spigot from the fermenting guile.

"V. If tapers of *unequal* heights be placed in a tumbler, and this gas be poured gradually into the vessel, the lowest will be first extinguished, and the others in succession.

"*Ration.*—This shows that the gas will repose in the lowest stratum of the atmosphere of a mine. It also illustrates the phenomena of the Grotto del Cane, near Naples.

"VI. Phosphorus previously kindled will burn with a lambent flame in this gas, and the mingled vapour will render the gas visible.

"VII. A wide-mouthed phial or cylinder entirely immersed in this gas will be filled with it, the previously contained air being displaced by the heavier gas."

We recommend, with great pleasure, to our professional brethren Dr. Murray's little book. It is certainly well executed: it is partly, as the author frankly confesses, a compilation, but interspersed, we must add, with many useful and judicious reflections.

FOREIGN MEDICAL LITERATURE.

Memoir of the Epidemic Dysentery of Maine-et-Loire in 1834, presented to the Medical Society of Angers.

BY J. GUÉRETIN,

First In-door Surgeon of the Hôtel Dieu of that Town.

THIS Memoir does not give an account of the epidemic, but a summary of cases observed by the author himself, with some additional information collected from other practitioners,

but in a manner too vague to be satisfactory; on two points, however, the Memoir deserves especial attention.—first, on the anatomical alterations, and, secondly, on the use of neutral salts as the mode of treatment.

In twenty-five post-mortem examinations, M. Guéretin asserts that he uniformly found wounds in the large intestine, which presented the form of turgid swellings and of ulcerations, the former much resembling urticarious patches, of a greyish or blackish hue, the fainter discolouration appearing to be the first shade of the second, and exceedingly like gangrene of the mucous membrane; yet this membrane he never found in a gangrened though frequently in a slightly softened state, especially between the greyish swellings; and this appearance, at a time when the morbid alterations in this malady were not so well understood as at present, led many to the belief and assertion of gangrene of the mucous membrane of the rectum being often found in this malady.

Antiphlogistic treatment, according to M. Guéretin, had not the effects usually wrought by it in affections purely inflammatory: opiates succeeded in some cases, failed in others, the effect in all appearing to vary with the locality. But on the use of neutral salts he insists much, avowing at the same time that he did not employ them in the first stage of the epidemic, its symptoms then being so intense and alarming, it spread so rapidly, that neither he nor any other practitioner would venture to administer purgatives; doubtless deterred by the opinion still generally held in the profession, that purgatives have no effect but that of irritating the intestinal mucous membrane. It was therefore when the epidemic had lowered in intensity, and all its symptoms had become of a less aggravated character, that M. Guéretin had recourse to the treatment by neutral salts, so that we are absolutely without data as to what their operation might be if used at the point where all other medications were found to fail, and where consequently their efficacy or nullity would have been best ascertained. On the malady in its ameliorated state, their effect was as follows:—

The salts administered pure, or mixed with an ounce or two of manna, from two drachms to one ounce of sulphate of soda or of magnesia, were followed in the course of a few hours by evacuations, easier, more liquid, and abundant, and especially less sanguineous; tenesmus lessened. The affection in the greater number of patients did not increase, and the liquidity of the evacuation commonly disappeared from four to eight hours afterwards. With about half the number of patients there was a relapse in twelve or thirty-six hours, which yielded only to a fresh dose; in short, the neutral salts were found to ameliorate, but never to aggravate the symptoms of the malady under any circumstances. But the most noticeable point is the influence of locality in their result, of which M. Guéretin

cites many examples. Patients, he says, living in districts unfavourable to the operation of salts, on removing to more favourable spots, have derived full and immediate benefit from their use.

History of the Epidemic Dysentery in Bretagne.

BY MM. VERGER AND CHAUVIN.

The authors begin their memoir with a complaint of the indifference with which facts tending to illustrate the rise and progress of epidemics are too often overlooked in the provinces. The complaint, though much too general, is just. The *Gazette Medicale* has indeed furnished a great number of valuable documents on the subject, but much yet remains to be done. In truth, great benefit would result to science were the appearance of every epidemic noted down, and its progress studied by the periodical medical press. But first, the doctrine which identifies the same malady in every case, must be entirely done away with, a doctrine which, if not professed, is at least admitted by the school of Paris.

The memoir of MM. Verger and Chauvin contains some researches on epidemics in general, which belonging to general pathology are not at this moment of interest, and the epidemic of which they treat having long since subsided; another letter also being announced by them on the same subject, we shall forbear, until after the publication of that document, to make known the facts which may probably prove of some importance to the progress of science.

Colica Pictonum accompanied with severe Cerebral symptoms—Obscurity of Diagnosis—Death—Remarkable Alteration of the Intestines.

COMMUNICATED BY DR. LEBATIER.

— Gruneberg, 15 years of age, was admitted into the hospital on the 5th Feb.; he had been inoculated three times, but no eruption had ever appeared. A few months prior to his admission, he had been employed with several other lads in the manufacture of silver and gold-gilt paper; all of them had from time to time suffered colics more or less violent, and many had in consequence been obliged to change their employment. Gruneberg himself usually eased his sufferings by drinking sugared milk, but was at length obliged to go into the Hospital of St. Louis, whence he returned at the expiration of six days tolerably well recovered.

Feb. 2nd. After a night of great agitation, he was suddenly seized with violent cephalalgia, vertigo, and dilatation of the pupils.

5th day of his admission. Answered fitly to all questions; pressure on the abdomen relieved rather than increased the suffering; painful numbness of the limbs; pulse rather raised and frequent; cephalalgia much lessened: treatment as for metallic colic. During

the night, agitation, approaching delirium, copious vomiting, prostration of the upper members; pulse 112 to 115, strong and vibrative; twelve ounces of blood taken from the arm.

6th. Still the same prostration; strong pulsation in the crural artery; the slightest pressure on the muscles of the thigh painful; no evacuations; slight mucous rattling in the chest. Eight leeches were applied during the night behind each ear; no sleep; pulse 120.

7th. Pulse 80; squinting at intervals; deglutition difficult; tongue moist, and rather white.—Purgative lavement, seton in the nape of the neck, blisters on the thighs, ammoniac blister on the forehead.

8th. Variolous eruption; pimples red, prominent, and papulous, covering the whole body, and more particularly thick over the face and upper members; a nettle-rash also appeared on the arms, right shoulder, and parts of the back; many of the urticarious patches were red, others pale, all prominent, fore right arm covered with them; the variolous pimple centred within the urticarious patches, but he had no seeming consciousness of either pruriency or heat in them; pulse 84; sinapisms were applied to the legs; general state of sensibility obtuse, and so continued; cerebral symptoms the same. The variolous eruption progressed pretty regularly until the 17th, when the general symptoms became worse; pupils less contractile; head thrown back; teeth and gums fuliginous, and on the 20th he died. Forty hours afterwards, the post mortem examination presented,—

Skull.—An incision of the membranes of the brain was followed by a flow of serum, of which the veins to the left were fuller than those to the right, each ventricle containing about a teaspoonful.

Thorax.—Lungs normal; dilatation of the right ventricle; and the left presents a concentric hypertrophy.

Digestive Organs.—The stomach presented many deep furrows, much thickened, and slightly softened; the small intestine with isolated follicles and some patches, more discernible towards the cæcum. In the large intestine Brunner's follicles were more developed; on the valves they were black, protuberant in the centre, and the size of a small lentil seed; in the larger colon and in the rectum, these projected various heights, were diametric, and in great numbers; these projections, somewhat like the tubercles formed under the skin, were of a brownish green colour, striated with dingy white; summits ulcerated, edges unequal and notched, not softened but rather resisting the knife beneath the ulceration. Nothing abnormal in the rest of the organs.

In the above case we may remark that during life there were two totally distinct maladies, metallic colic and small-pox; but the post mortem examination presents a complication of maladies seldom found, and accounts satisfactorily for the force of those symptoms

during life, which were inexplicable either by metallic colic or small-pox, namely, the alteration of Peyer's glands, to which it is far more natural to attribute the cerebral affection; the intensity of the febrile symptoms, the adynamic state, and, finally, death itself. And, further, this alteration of the glands, the immediate cause of death, though unknown during life, was revealed by an observer, on whose exactitude the most perfect reliance may be placed.

Considerations on Impotence as a cause of Nullity of Marriage, with Reflections on Fecundation.

BY M. BEAUDE.

An interesting cause in the *Legal Medical Report* gave rise to M. Beaudé's considerations; but we will first give a concise summary of the facts.

In 1822, Miss N— was married to the Sieur X—, and some years afterwards sued for the dissolution of the marriage, alleging as the reason, that her pretended husband was a man only in name, had not the male organs of generation, and, moreover, was regularly visited by the monthly incommidity to which females alone are subject.

The Tribunal, much struck with the fact, gave, in April, 1834, the following judgment: "As no marriage is legal between two persons of the same sex, the petitioner must prove the facts which she alleges; and the person of the Sieur X. must be submitted to the inspection of M. A. Dubois." The result of this personal scrutiny is given in the *Report* for July, 1834, and nearly in these terms—"The Sieur X. is a male; has two testicles like other men; the appearance of a penis, though very small, ill-formed, and without the urethral canal; it exists, however, though not in its right place, and by its position incapacitates the Sieur X. from performing the necessary function of conveying the semen to the orifice of the vagina, and thence to the uterus; and, briefly, the truth is, that the Sieur X. has not, never has had, never can have, the powers necessary for the propagation of his species.

"It is however true, that, to an eye unaccustomed to the view of such conformations, the Sieur X. has, at the first glance, the semblance of a woman, but an attentive examination, aided by anatomical skill, readily ascertains that each division of the scrotum (somewhat resembling one of the great labia of a woman) contains a testicle, the cord of which is easily traced towards the abdominal ring on each side, and that which at first view might appear a large clitoris, is in fact a small penis, without, as before stated, the urethral canal. On raising that which has the appearance of two large coverings of a valve, the small orifice of the urethral canal is perceived at the bottom, very distant and beneath the penis; this position of the orifice, and it is merely an orifice, having no length, must oblige the individual

so formed to squat down when he urinates lest he should wet himself.—A. M. DUBOIS."

In consequence of this report, final judgment was awarded on the 17th of last December, and to this effect:—

"As the Sieur X. is really of the masculine gender, the defects of his conformation, whatever they may be, do not nullify the marriage; and this doctrine is in conformity to the spirit of the civil code, the object of which is to put a final stop to the scandalous processes founded on the impotency of husbands, which were wont to take place under the ancient legislation.

"The Tribunal declare Madame X. nonsuited, with costs."

M. Beaudé arraigns the justice of this judgment. "Nothing," he observes, "can be more clearly evident than that the Sieur X. is a man only in name; where then is the moral propriety in condemning the woman to live with such a shadow? Does the Tribunal, whose modesty takes the alarm at the bare recollection of the ancient legislation, consider adultery, the only compensation left to the woman, as so innocent an alternative, that it may be, as it were, prescribed to her by their judgment? Again, it was under the ancient legislation that impotence arising from mal-conformation was exempt from the scandal attached to that which arose from other causes. In short that the civil code which on that point differs from the ancient, did formerly permit divorce as an alternative; and now that divorce is abolished it ought necessarily to return to the spirit of the ancient legislation."

To these arguments, the drift of which cannot be denied, M. Trebuchet adds others in a letter on the same subject in the succeeding number of the same Journal.

Whether from negligence or fear of scandal the civil code does not mention impotence among the causes of nullity of marriage, it confines itself to the general expression *error of the person*, without giving any intimation of what is to be understood by those words, nor is any to be gained from the discussions which took place at the time of its compilation, except that by *error of the person* is not meant a mere error with reference to the qualities, fortune, or condition of one of the contracted parties. But this M. Trebuchet thinks is too rigorous an interpretation; would there not be error in the person, he observes, if, with the natural view in marriage, a woman marries and finds her husband an eunuch?

But the more decisive argument is perhaps this:—The contract of marriage is subject to the general rules of all contracts, one of the most essential being—consent to it; which becomes null and void if given under error, or obtained by deceit (Code Civil, art. 1008-9). If the parents and woman had known that the intended husband was radically deprived of the signs of virility, would they have consented to the marriage? Certainly not; therefore, the consent having been obtained by

culpable deceit, becomes null, and of course the act which is the consequence of it. So thinks Merlin; and Toullier, waving the consideration of impotence which may supervene posterior to marriage, is of opinion that real impotence preceding that contract nullifies it. First, because Art. 312, Code Civil, permits the husband to disown an infant, if at the moment of presumed conception he was, by the effect of accident, incapable of cohabiting with his wife. To these imposing authorities may be added that of the Cour Royal of Treves, which annulled a marriage in 1808 on similar grounds. As physical causes and defect of conformation are the obstacles which oppose the natural and legal aim of marriage, it is of right annulled. Secondly, the nullities mentioned in the Code Napoleon have evidently no bearing but upon the cases foreseen by the same Code.

But, on the other hand, the general opinion of the courts and tribunals of the present day is against these causes of nullity; and authorities are not wanting in opposition to those of Merlin and Toullier. Favard de Langlade, for example, holds an opinion directly the reverse; so that even M. Trebuchet himself, though seeming inclined to the admission of these nullities as valid, remains still in doubt. This strife in opinion amongst such respectable and competent authorities warns one to circumspection and reserve; a few observations, however, may be permitted.

The Law Report peremptorily avers that the Civil Code does not admit impotence, even from mal-conformation, as a nullifier of marriage: thus they allege *error of the person*. But are there not very many deformities of persons, which, if known, would prove preventives to marriage? but which, nevertheless, can scarce be classed as error of the person, or denominated deceit. Waving those personal deformities, so carefully concealed, what if extreme narrowness of the pelvis oppose an invincible obstacle to the hopes of maternity? Would it be considered as a nullifier of marriage? In the majority of cases it would at least stand a pretty fair chance of operating as a preventive to marriage.

A more weighty consideration is, that the law, in maintaining the marriage, permits the mal-conformed husband to disown the offspring of it, since it is always in his power to prove his incapability of cohabitation. But even this argument appears so little peremptory to Toullier, that he applies it only to cases of impotence before marriage. Whether before or after, are not the dangers of it the same? The clearest point of the whole reasoning on the matter is, that the authors of it, recognising a material defect in the Code Civil, have generously supplied it, and have tortured the sense of the law to make it say what it does not mean. The Tribunals have not ventured to act upon such perilous interpretation;—we, therefore, cannot entirely coincide with the opinions of our honourable associate M.

Beaude. He gives, it is true, due credit to the primitive code, which granted divorce as an alternative; but even that could not in the present case have been demanded but by mutual consent of the parties; and why, then, should he be inculpated if he does all that his organisation permits him?

But M. Beaude is, we think, perfectly right when he exclaims against the iniquity of such a result. The judgment of the Tribunal was right, but the law which guided them altogether detestable. The Legislature ought to interfere, and hasten its correction; and we ardently hope, therefore, that M. Beaude's appeal to it may not be made in vain.

When we consider the question scientifically, we cannot fail to see that part of the error of the law rests on the science of anatomy and physiology. The first inquiry made and solved on the examination of a monster is, of course,—Is it a male or female? Neither anatomy nor law acknowledges more than two sexes; nevertheless, it is well known, and is again demonstrated by the case in point, that there is a third variety of the human species called *hermaphrodite*, that is, both male and female, or, more properly, it would be named *anhermaphrodite*, neither male or female, which is the absolute fact. Now, if this view of the matter were admitted, it would naturally, properly, and entirely, rectify the error of the law. Thus, in the Report, otherwise so precise and judicious, of one of our most learned men, instead of finding *the Sieur X. is a male*, which is not rigorously true, we had seen *the Sieur X. is neither male or female*, the marriage would have been declared null, since the law only permits marriage between persons of different sex; law and equity would then have accorded, and without disparagement to science.

This discussion throughout has had reference to prodigies only. Another case may occur; and although we no longer mutilate our children for the service of operas, or the pleasure of monarchs, we have actually eunuchs, become such from accident, vengeance, or malady, or from one of those horrible operations for the cure of hernia still tried in our provinces by the wretched sufferers. If, then, an enuch concealing his state were to marry, ought the marriage to be annulled? The Code is silent; the decision is remitted to the entire arbitration of the man of art who is summoned to declare, whether the husband be of the masculine gender? Truth obliges him to say, that he has been, but is no longer so. Yet another, and a nicer question, since even M. Toullier himself has failed to meet it with the same courage he did the first,—whether the loss of virility after the consummation of marriage be not also an available cause of nullification? To us it appears that the solution of the first question inevitably gives the second, the same arguments having the same weight on both sides; and every part of the discussion proves the neces-

sity of re-establishing and completing the law of divorce. We cannot wind up this article better than in the words of M. Beaudé, "Let us hope that the day of justice will at length dawn, a day as anxiously looked for by the friends of morality as by the friends of humanity."

Memoir on a new sort of Medicated Cushion-Bandage for the Radical Cure of Hernia.

BY DR. JALADE LAFOND.

In former times, when surgeons had renounced those painful operations by which they intended to prevent the recurrence of hernia, the treatment of that affection remained almost entirely palliative, and it is only within these few years that they have again turned their attention to its radical cure. Not to mention the brilliant but perilous operation of M. Belmus, others have attained the same end by permanent compression, aided by a prolonged recumbent position; but this condition brings with it extreme constraint and weariness; pain and even danger of short duration are preferred by the greater number of sufferers to a prolonged treatment, however easy and certain it may be.

Such being the state of the matter, the first question arising is,—is the horizontal position really indispensable? In standing or walking, the abdominal viscera press more on the hernial openings than in a state of repose; still there must be pressure, and certainly the action of a proper bandage well adjusted is in this state the first curative power; indeed by it alone cures have been successfully performed, chiefly among children and young people.

M. Jalade Lafond has followed up this idea; but, never trusting to it singly, has imagined the union of it with a medicinal action. Accordingly he has invented a bandage, the cushion of which may be rendered hard or elastic at pleasure, and containing a reservoir for the medicated substance. The cushion elliptical and convex is bored in the interior with an elliptical cistern composed of four elastic plates, resting on, and rivetted to, a fifth; the bottom is pierced with a great number of little holes like a sieve, and the whole is covered over with prepared Indian rubber, pierced also with innumerable holes for the issue of the medicated substance to the skin. The medicament is introduced into the cushion by an exterior hinge, supported by a sliding bolt. The power of the medicament, which ought to be astringent, is modified as occasion requires.

Thirteen detailed observations verify the success of this invention; ten of the cases were inguinal, intestinal, or epiploic herniæ, of from three to more than twelve years' standing, in subjects from fourteen to forty-seven years of age, requiring from two and a half to six and a half months for the cure; in one case only, two years; in another, the hernia disappeared but the ring remained, and it was

thought prudent to continue the use of the bandage. Two other cases of umbilical hernia, the one of ten years, was cured in five weeks, the other, of a date not quite so ancient, required four months for its disappearance; and, lastly, a case of crural hernia, the consequence of labour, disappeared totally in the course of three months.

From all which it appears that the duration of the treatment is variable, depending neither on the age of the subject, nor on the date of the malady, and we add, nor on its nature; some occult influence there must be, arising, it would seem, from the constitution of the subject, as neither the size of the hernia nor the extent of the opening account satisfactorily for such a variety of results.

In general the treatment is simple, and without symptoms, but several times inflammation of the integuments supervened, pains in the abdomen and in the iliac fossæ, and once also violent inflammation in the abdomen, which, however, soon subsided. Did these symptoms arise from the action of the medicament, or from the pressure of the bandage? We think, the cutaneous irritations excepted, the bandage was the cause of all. M. Lafond notes a case himself, in which the pains returned immediately on the recommencement of the pressure; in all cases the treatment should be suspended until the symptoms have disappeared.

It now remains to be inquired, what share in the cure had the medicament, what the bandage? M. Lafond, who could best make answer, has not yet thought fit to touch upon the question. To us it appears that the bandage had the greatest if not the sole agency in the success.

It is necessary here to observe that the author has not, we think, given sufficient weight to certain precautions. Most of the patients who came to him wore bandages, ill-formed as to the cushion, or of too weak a spring; now he especially endeavours to make the pressure equal and perfect on all the points necessary. We are therefore inclined to think that had those persons been fitted with suitable bandages, the radical cure would have been more frequent. A proof in point occurs in the author's eleventh observation: a man, forty-five years of age, with an entero-epiploic hernia of prodigious size, and of twelve years' standing, which had been considered as adherent, had a circular bandage, which was properly adjusted, and which consequently, renewed but once, sufficed to obliterate the ring.

When the obliteration is ascertained, the apparatus must not be altogether removed. M. Lafond then applies a bandage of a gentle and continued action that supports the obliterated ring and favours its consolidation. For this purpose he has invented an air cushion.

Reports of Societies.

WESTMINSTER MEDICAL SOCIETY.

Saturday, March 21st, 1835.

Dr. ADDISON, in the Chair.

THE members present returned their unanimous thanks to Dr. Addison for the valuable remarks offered by the Doctor on auscultation at the two preceding meetings.

Dr. Johnson then related a remarkable case of a young gentleman, *ætat.* 22 years, who had previously enjoyed, up to the period of the attack, sound health. Febrile symptoms first presented themselves without any organ being in particular implicated more than the rest. However a determination to the head, accompanied with typhoid symptoms, ensued, followed by an alarming hæmorrhage from the bowels, filling three or four large utensils. The delirium subsided, but great debility with a small quick pulse remained. The patient was an only son, and his parents were very anxious for the doctor's prognosis. A favourable one was given, as he considered that hæmorrhages, occurring under such circumstances, did not prove fatal. The gentleman rapidly became convalescent. Suddenly a new phenomenon manifested itself, where both ankles became affected, but exhibited no external inflammatory characters, such as swelling, heat, redness, excepting an exquisite sensitiveness, so much so that the sufferer was compelled to lie with his legs uncovered, the weight of any clothes being insupportable. The remedies prescribed afforded not the least relief. The sensitiveness all at once disappeared, but the same train of typhoid symptoms set in, accompanied with a second hæmorrhage, but not so profuse as the first. The plumbi-superacetates, combined with opium, followed by small doses of the *magnesia sulphas*, were ordered. The second day there was no hæmorrhage, but symptoms of low fever with delirium continued. On the fourth day the hæmorrhage returned, and the patient sank. Permission was not granted to inspect the body.

The President requested to know whether calomel had been administered, as he considered it was often prescribed without due care.

Dr. Johnson replied it was given, but not to any extent.

Mr. Horne said he did not rise with the intention of contradicting Dr. Johnson's opinion as regarded hæmorrhages, or putting his small experience in the balance against the learned Doctor's. But a case of typhus had lately come under his notice, in a youth aged 14 years, where the disease was going on to convalescence, and most unexpectedly a fatal collapse took place, for which Mr. H. could assign no cause; nearly half a pint of a gin

was poured down the throat without any benefit, death ensuing about two hours after the sudden change. On throwing off the bed linen the mischief was found to arise from a hæmorrhage from the bowels to an almost incredible amount. The viscera examined were healthy, except the mucous membrane lining the alimentary canal, which was softened and at one place partially ulcerated. Before sitting down the speaker remarked, that he was not aware that his case was an exception, and he also believed that authors were not silent on the subject.

Mr. Elwyn alluded to a case of typhus, which had been received into the Middlesex Hospital, under the care of Dr. Watson, that proved fatal after hæmorrhage from the bowels, where an ulcerated state of the mucous membrane was detected.

Mr. Taylor made some remarks on the same subject, and in favour of the last two gentlemen, but he spoke so low that we could not follow him.

Dr. Johnson inquired if any member had witnessed the surprising effects of Ruspini's styptic in arresting hæmorrhages, not that he was an advocate for patronising quack nostrums, but still he must confess that this possessed extraordinary power, although perfectly tasteless and colourless, and apparently harmless where its astringency was not required, for he had himself swallowed a tablespoonful, that being the quantity directed to be taken according to the printed directions, without experiencing any change.

Mr. Chinnock replied that he had tried its power with the happiest result, especially in a case where hæmorrhage followed the extraction of a tooth, in which case every known remedy was previously had recourse to without arresting it. Mr. C. recommended also the administration of turpentine.

Mr. Watson has used it, through the suggestion of Sir B. C. Brodie, in a dangerous case of epistaxis, that had baffled every remedy for several days, but whether the benefit procured was attributable to the styptic, the time that had elapsed, or from its being last employed, he would not take upon himself to determine, but such were the facts.

Mr. King considered its power depended on its simplicity, for he was fully convinced that we frequently met with disappointment, from the styptics generally employed being too potent; for, after the failure of strong acids, he had frequently seen vinegar and water speedily put a stop to the discharge.

The hæmorrhagic discourse having subsided from exhaustion, when, like nature, capricious in her actions, from a subject that had a tendency to produce calmness, nay even death, the spark of life was aroused into hysterical convulsions, through the recitation of a case that Dr. Johnson had visited at 5 P.M. this day. The subject of the case was a young lady, who had been disappointed in love. She would suddenly fall into a state that apparently

closely approximated to death, but on the slightest touch, even with the point of a finger, she would be thrown into the most violent and distressing convulsions. In this almost lifeless state she would remain for several days without partaking of any nourishment; the present inactive condition had lasted upwards of thirty-six hours. Suddenly animation would return, she would dress herself, laugh and talk, take some refreshment, ask for her medicine, which was composed of the most disagreeable ingredients, such as assafoetida, camphor, &c., and then, perhaps, would as suddenly experience (query, produce?) a relapse. Every means that possibly could be thought of have been tried, without deriving the least benefit. Dr. Johnson recommended her friends to have recourse to no further treatment, but wait patiently, as he believed a suitable marriage would be found to prove the best remedy.

A member recommended for hysterical affections, during the paroxysms, cramming the mouth with common salt; from the good effects arising from its use in these, not unfrequently feigned cases, he had been induced to try it on a poor lad, whom he found lying on the floor in a state of insensibility, from a severe beating which he had received over the head. The salt had no sooner been administered than the poor lad started up, and walked away perfectly recovered. The gentleman said he would not take upon himself to explain its *modus operandi*.

Mr. Toynebee said that he had lately witnessed its power in recovering a dog, of the Newfoundland species, where the poor animal had suddenly fallen down in a state of insensibility; a groom who had called for the salt, although aware of its efficacy, was ignorant of its action.

Mr. Mart considered that its *modus operandi* depended on the sudden shock it communicated to the system; from practising in the navy he had often had occasion to behold the good effects derivable from sudden shocks, as not unfrequently the sufferers would inadvertently fall overboard, the result was an immediate return of consciousness and recovery. However, he considered Jack Tar had a better and a more effectual remedy than salt, and that was dashing a well-soaked mop against the glutens.

Mr. King advised pouring boiling water, sufficiently heated to destroy the epidermis, in preference to dashing, from a height, cold water to arouse the *vis vite*, whether the insensibility was dependent (we believe) on a physical or accidental cause; if the former, and especially if the insensibility arose from the brain being either functionally disordered through sympathy, or organically diseased, we should much question the propriety of this treatment.

The Society then adjourned, Mr. Strettor having promised, by the request of the members, to bring forward at the next meeting the subject of small-pox for discussion, Mr. S.

having made some valuable remarks on the subject at the hour of adjournment.

LONDON MEDICAL SOCIETY.

Monday, March 23rd, 1835.

Dr. WHITING, President, in the Chair.

The case of calculus, related by Mr. Stevens at the Society's last meeting, having created considerable interest, it led Mr. Clifton to collect further particulars, when he found that a female patient had been operated on by Mr. Stanley at St. Bartholomew's Hospital in August last, and from various coincidences he did not doubt but that it was the same individual, but regretted that Mr. Stevens was not present to corroborate it. From the irritability of the urethra it was found impracticable to use Weiss's dilator, therefore a valvular incision was made, and a calculus extracted (query, size, composition?), which in part crumbled under the forceps, from the nucleus being composed of matted hair*. The calculus is preserved in the Museum belonging to the hospital. After the patient left the establishment she was visited by Mr. Stanley, and the incontinence of urine was found dependent on the formation of a second large calculus, which she refused to have removed, and then this surgeon withdrew his attendance.

Mr. Headland submitted to the members some questions respecting the beneficial and prejudicial effects arising from persons accustoming themselves to the habitual use of opium. Some lengthy remarks were made by the mover of the subject, which have long since been offered by authors who have endeavoured to elicit information on this important topic, therefore we shall confine ourselves to what Mr. H. considered as practical facts, that he had obtained from paying no small attention to it for the last eight or ten years. Mr. H. had arrived at the conclusion, like most others, that opium taken in small quantities, for however long a period, does not tend to shorten human existence, on the contrary if taken to excess. By bringing the subject before the profession he flattered himself he should be able to obtain for the habitual opium consumers, the quantity considered, an equal right to accomplish the insurance of their lives, as well as those individuals who are in the habit of taking half a pint to a bottle of wine daily, as he regarded the practice pretty much one and the same thing. For in all insurance documents it was stated, that information was requested on this point, and of course whether the quantity taken proves either beneficial or injurious, it invalidates the applicant.

Mr. Headland had attended a wealthy gen-

* It still remains a query how the hair go into the bladder.—*REP.*

tleman since 1828 to the time of his death, which lately took place, *ætat.* 35, who appeared fully 50 years old, he was subject to rheumatism, and at the time of his first being consulted the patient was taking daily an ounce of Battley's liquor opii sedativus. The sufferer was fully conscious of the ravages the bad custom produced on his system, and to cut short his miserable existence he resolved to put an end to it. With this intention he placed himself by the brink of a rivulet, and swallowed a full tumbler of the preparation. The increased quantity, to the patient's surprise, lengthened the stage of exhilaration, and consequently shortened the depressing or suffering stage. Being foiled in his attempt of committing double suicide, by the combined powers of poisoning and drowning (the first that we remember having met with, where both powers bid fair to work their destructive influence at the same time), he returned home, continued the mal-practice in spite of Mr. H.'s remonstrances. However he prevailed upon him to substitute the acetate of morphia; the first day he took only one grain of this salt three times in the course of the day, without experiencing any effect; next day six grains; third day twelve grains, the latter quantity however he could not bear. Within the last year and three-quarters of the patient's life he consumed one pound, two ounces, and odd grains of the acetate of morphia, a quantity Mr. H. believed had not its parallel. The symptoms that he would particularly call the attention of the Society to, were a prominent eye and contracted pupil, and, after death, to the accumulations of fat that were found adhering to the cellular tissue, so much so that he had observed in a patient, who had laboured under an ulcerated womb, which caused the total destruction of that organ, the intestines were found buoyed up in their natural position by an immense lump of fat. This lady, to obtain ease and sleep, had accustomed herself for a length of time to very large doses of the drug. The other symptoms that he had remarked were difficult respiration, a trembling pulse, constant loss of appetite, and vomiting; the latter he attributed to a regurgitation of bile, and the loss of appetite to a suspended action of the absorbent vessels. Mr. Headland had attempted to effect the insurance of his patient's life at several offices in this metropolis without avail.

In answer to a question from Mr. Dendy, Mr. H. replied that the sexual propensities were entirely annihilated, and his patient had never been married.

Mr. Whitehead remarked, that he had had a pauper patient, but he proved a very expensive one to the establishment where he applied for assistance, as he took ʒj. of pure opium daily, who attained the age of 64 years, but did not affect his procreative powers, nor did Mr. W. believe that opium tended to shorten life.

Dr. Johnson believed that Mr. Headland

laboured under a great mistake with respect to information being required by the directors of the insurance offices, whether the applicants were in the habit of taking opium, for he had been physician to an office now eleven years, and he had never heard of it. But, on the contrary, if an individual took it for the relief of any neuralgic or stomach affection it would tend to lengthen instead of shorten, by improving his life;—so much for the medico-legal question. As to the physiological one he could not agree, but considered it to arise from the same cause that affected habitual drunkards, who scarcely ever failed to vomit up the contents of the stomach, after the excitement, produced by the stimuli, was gone off; and as to persons becoming fat, that was quite in opposition to his experience.

Mr. Headland replied, that he considered himself supported by the case of some great person in Scotland, who had insured his life, where the directors refused to make good the demand on them, from his life being shortened through his indulgence in opium, and further explained that the fact was not suspected during life, for they evidently appeared emaciated, which was corroborated by finding after death all the muscles of the body considerably wasted, which appeared paradoxical, but so he had proved it.

A gentleman requested to know if Mr. Headland did not allude to the Earl of Mar's case, which was answered in the affirmative; then the inquirer begged to correct the Secretary. For in the civil suit, regarding Lord Mar's insurances, the insurance company was found not entitled to refuse payment, on the grounds that the directors did not make sufficient inquiry into his Lordship's habits, the habit having been contracted prior to the insurance being effected. The gentleman further stated, that, having made various experiments with opium for some years past, he perfectly agreed with Dr. Johnson that opium produced emaciation, nor had he found that those persons, who had broken themselves of the habit, while in the prime of life, regained their flesh, therefore he considered Mr. H.'s two cases as exceptions.

The President, in announcing the termination of the discussion, related the case of the Rev. — Hall, a most eloquent and popular preacher, who for many years habituated himself to the use of two ounces of laudanum daily, which produced a liveliness in his discourse that all his hearers admired, without inducing the least unpleasant feelings, or proving prejudicial to his health.

EFFECTUAL CASE OF TRANSFUSION.

THE life of a poor woman, wife of a labouring man, at Clare, was lately saved, when in the last stage of exhaustion after confinement of her tenth child, by infusing a portion of blood from the arm of her husband into his apparently lifeless partner. She is now doing well.

THE

London Medical and Surgical Journal.

Saturday, March 28, 1835.

COMMENTS ON THE BRENCHELEY CASE
OF LITHOTOMY, NEW IN THE
ANNALS OF ENGLISH SURGERY.

THE Brenchley case of lithotomy (so called), the leading features of which we recounted in a late number, has excited a more than common share of both public and professional attention. The question, bearing upon the right of forcibly operating upon an adult and sane individual, has been freely canvassed, and the professional acumen of our brethren directed to a novel, and we hope never-to-be repeated, point for discussion.

Of course, among the number who have considered this subject differences of opinion on it may be expected, and accordingly, among those with whom we have communicated, a very diminutive minority have advocated a most limited exercise, in certain cases, of the abhorrent system, while the grand majority have held the negative position, and in the most unqualified terms denounced it altogether. Among the public the general feeling seems to be, that surgical operations, inflicted by means of coercion and personal violence, are to the last degree to be condemned, and that the objection holds with double force when intrigue, or jealousy, has been instrumental in the flagitious transaction; that they will, if tolerated, lead finally to most lamentable consequences, and encourage a system of wholesale cutting into human flesh, where disease is present, which will be bounded by no other responsibility than that of a few, often in country localities *brutalised*, beings, invested with parish authority. This some may pronounce to be an ex-

treme conclusion, which the intellectuality of the age will not permit to be perpetrated. But there is danger, nevertheless, when the liberty of the subject is concerned, that an abuse against it, left unpunished, or without severe animadversion, may in proportion to its impunity grow to a more serious extent.

Taking this view of the subject, we propose examining the circumstances which may allow of — palliate, or seem to palliate, the recourse to forcible means in surgical operations. The laws, either statute or common, will not afford us much assistance in the execution of our purpose.

The most obvious instance, in which coercion *in an operation* may be tolerated, seems to be when insanity is produced by some cause removable by the surgeon's art, or when some accident occurs which places the patient's life in immediate danger. In either of these cases the party is so placed that his presence of mind is gone, and his intreaties, or resolves, should not be so much consulted, or have that weight in restraining others in their exertions in his favour, which, under other circumstances, they might be allowed to have. It seems but reasonable, and therefore (should be) lawful, that in such cases help should be afforded even against the patient's will.

Infants again, as far as the mental power is concerned, are deemed incapable of judging, and therefore it is lawful that their *immediate* guardians should have the power of determining for them, and enforcing submission where it is for their benefit to undergo a surgical operation; but there are shades of distinction in these cases: such as when the supposed cause of insanity (be it a tumour or other removeable substance pressing upon the sensorium) is but indistinctly made out,

and the operation might, from the imperfect diagnosis, produce no effect, or a bad one; if the doubt were great the operation would be unwarrantable, and should be accordingly punishable. In infants, subject to the controul of guardians, parents, or otherwise, no operation should be esteemed legal, unless sanctioned by a consultation of qualified medical men,—reasons start up on every side to render this caution advisable.

Again, passing over those emergencies, which involve life at a moment's warning, such as the wounds of any great artery, the bursting of a large aneurism, or violent discharge of blood in any way; a secondary grade of accidents is liable to occur, such as fractures, dislocations, and greater or lesser lesions of the flesh, not including the larger vessels. In these, the mental strength of the sufferer remaining, his wishes ought undoubtedly to be consulted, and nothing should be done for his relief against his inclination, that sacredness of the person, which the ancient Saxon laws insured, but which was in a great degree destroyed by the brigandage of the Normans, should be strictly respected. But if a man rather choose to die than submit to have his wounds dressed (we consider a self-immolator to be always insane), the saneness of his mind, we think, might be fairly impugned. It then might be a question, whether or not, after delaying to the last serviceable moment, the cure might not be attempted under so much restraint as was absolutely necessary. In all these cases the surgeon should be held responsible *quoad* the necessity and performance of the operation, or there would be no safety against the reckless daring of ignorant pretenders, or the stupid ambition of such as covet the fame of being esteemed *clever* operators, forgetting that the use of the

knife in surgery is one of its opprobria, and that it becomes disgraceful and even criminal, in an immeasurable degree; when used unnecessarily.

Having now considered the circumstances under which, if at all, coercion might appear defensible, we come to those in which its exercise is not only illegal, but militates against the universal opinion of mankind, and gives a shock to one of our best feelings, that of self-respect. Of this class, we are of opinion, are complaints of a chronic nature, whether slowly and inappreciably undermining the powers of life, or progressing with a quicker step; for the question in these, is not one of immediately vital importance, but whether the patient be willing to suffer more or less evil for an indefinite time. There is no reason why he should not use his own discretion here. In other concerns of life, as important as that under review, a man is left to choose his amount of good or evil as seems fit to him, and the same measure of indulgence might, without harm to the state, be conceded to him where bodily infirmity is the object. In fact, the guiding of all that regards his health is a right inherent in him; it is a right which even savages respect. It is that portion of his personal liberty which his relation to the social community in which he moves ought not in any degree to affect,—never to cause him to forfeit, unless stricken with madness.

To enumerate the instances in which this discretion should be allowed would be tedious, if not impossible; but we may safely include among them that in which a violent, and, as the verdict of a jury upon the case proves, an illegal degree of coercion was practised at Brencley upon the pauper boy, an inmate of the workhouse there. As lovers of justice, we must say that we feel gratified that

the jury have decided it to be illegal to drag a man gifted with his senses into an operating-room, to be cut and divided as seemed fit to interested parties. We say we rejoice in the verdict of the jury who tried the case—they have shown themselves *independent* men. For is it to be endured in this civilised country, that a being possessed of his judgment and able to use it should be dragged up to an operating table, hurled down, and then held upon it by the united strength of four ruffians, while the knife was applied by a fifth to his flesh?

“*Ferrum idem quod olim vulnus flebile fecerat.*”

Is it to be borne that while the fear-struck patient was clinging to the door-posts of the—to him, *Golgotha*—and appealing for mercy, his answer should be the rude grasp of a merciless band, resolved to overpower and compel him to submit to the laceration of his body whether he would or not?—A jury has said, No! and we re-echo the verdict, repudiate *such* surgery, and hope that the brand “guilty,” stamped upon one of its perpetrators, will act as a warning to future intriguers in the operating way. We trust to hear no more of quackish-minded parsons forsaking their proper avocations to attempt what they are incapable of, and, owing to their imbecility, condemned to flounder afterwards in a legal *hot-bath*. We devoutly hope to hear no more of *curling-iron forceps*, even though *flattened* at the ends by an ingenious *jobbing* blaeksmith; and finally leave the parties concerned in the outrage, convicted, or not convicted, to reflect on what might have been the verdict of a jury if death had ensued, as it was likely to do from the united effect of the *operation*, and the inflammation caused by the *excitement* produced by their rough usage.

PRIVILEGES OF SURGEONS, AND LICENTIATES OF APOTHECARIES' HALL.

FROM a correspondence between the Poor Law Commissioners and a Mr. John H. Barnett, of Farringdon, Berks, it appears that in that district one of the Assistant Poor Law Commissioners (Mr. Gulson) decided that no medical practitioner, not being a Member of the College of Surgeons in London, should be permitted to contract for attendance on the poor. Mr. Barnett, who is only a Licentiate of the Apothecaries' Company in the said town, resisted this dictum successfully, and, after some correspondence with the Poor Law Commissioners, obtained from them an acknowledgement of that privilege which never should have been impugned. The spirited conduct of Mr. Barnett in the affair has placed Licentiates of the Apothecaries' Company equally eligible with Members of the London College of Surgeons, so far as respects the attendance upon parish paupers.

Upon this triumph of Mr. Barnett, which was a just one, our contemporary the *Lancet* remarks—“In removing the objection of which Mr. Barnett complains, that gentleman may imagine, possibly, that the Commissioners have rendered justice to medical practitioners generally throughout England and Wales, but they will soon hear to the contrary from those practitioners who belong neither to the College of Surgeons in London nor to the Apothecaries' Company in Bridge-street.”

Now, if by the practitioners who neither “belong to the College of Surgeons in London, nor the Apothecaries' Company in Bridge-street,” the *Lancet* means such as are possessed of no diploma or licence from *any* accredited source, but who are entitled to practise from having done so

prior to 1815, we say they must be old hands, and not so fit for parish contracts as their younger and, *we must say it, better* qualified brethren. If such of the above are meant as have bought a bit of paper, called a *Diploma*, at the *London College of Medicine*, situated No. 9, Lancaster-place, Strand, for the magnificent sum of four guineas, we cannot say we pity their exclusion from the parish loaves and fishes, meagre as they are. But if such as practise without the Diplomas or Licences of the London College of Surgeons or Hall of Apothecaries, but yet possess licences from accredited sources, are included, we do not believe that the ban of exclusion will be enforced against *them*.

With respect to the first two classes, we consider them of the same calibre, since the only qualification required in the first to obtain the four guinea bit of paper of the second, is that they be *practitioners of any sort*,—a cow-leech having been in practice before 1815, and drugged a few patients to repose, would be eligible. The august humbug carried on at the London College of Medicine, under the Protean forms of Senate, Provisional Senate, &c., passes, without damage of brains, all such as wish, at the stipulated price, to wear its four guinea honours; in fact, the business may be done at any time through the intervention of a twopenny-post letter (vide the cover of the *Lancet*), only taking especial care to pay postage and enclose an order for the four indispensables.

Often of yore has the *Lancet* denounced, with apparently measureless wrath, the cut and dried system of diploma-granting, carried on at Aberdeen and other places; often has its *virtuous* phial of indignation been poured out against all corruption; and at one

time, when business was slack, every thing seemed to its eyes puriform. Its red-hot endeavours were to cauterise without mercy: witness the camp pitched by a few of its trusty retainers in the locality mentioned, No. 9. This was intended to crush that "father of corruption," the College of Surgeons in London. A Treasurer (be sure of it), a Secretary, with six letters of the alphabet after his lengthy name, a Senate, and a Provisional Senate, (*hæc caveto Romane!*) were elected, or, more truly, stood on tip-toe self-elected, and looking out sharply from certain parlour windows every Tuesday evening for customers.

The *Lancet* lauded the affair to the skies, and in glee prophesied by its means the speedy demolition of the "pestilence at Lincoln's-Inn Fields;" but the fulfilment of that memorable prophecy, like that of many others, is not yet come. The College of Surgeons stands where it did, and so does the *College* of No. 9.

We have, however, in some degree digressed, and must return to our subject. All we intended to convey by what we have said, was, that the said College of Medicine having no right to sell or grant degrees of any kind, its members, (God help them!) if there be any, are in no better condition than their *unpapered* brethren—they of the unlettered ilk before 1815.

Thus far we have gone into the subject because we shrewdly suspected when our contemporary stood not up when the question of a charter for the London University was moved, that something of this kind stuck in his throat, and prevented his uttering a syllable against a monopoly similar to, but more thriving than, that of No 9; we say similar, because jobbing and trafficking in degrees were at the bottom of both, and promises of future incorporations and power blazed alike from

the pigmy of Lancaster-place, and the dome-capped giant of Gower-street,—“*Arcades ambo*”—but their singing is spoilt!

After this preliminary we proceed to avow that we differ widely from the *Lancet* in its ideas of justice, so far as respects the admission of unlicensed practitioners into official situations. We hold that nothing can be more just or fair than to appropriate to the well-educated practitioner his undoubted right—that of taking precedence of such as pretend to understand intuitively, as many blacksmiths, farriers, &c., in different parts of the country pretend to do, an art for the attainment of which he has paid and studied deeply. We aver that if there be any office of profit to be filled by a medical man, the bearer should be properly qualified, and possess vouchers for the same; for is it reasonable that one who has perhaps never spent a shilling in his education, should rank with, much less take precedence of, another whose career of education has dived far into his finances? We opine not; besides, those who practised before 1815 have had sufficient time to put their house (brains?) in order, and to qualify themselves, if so inclined, as the law demanded. They would then have become on a par with their *qualified* brethren, instead of continuing to practise under a miserable subterfuge; and if they have neglected, as they *have for good reasons*, to do *this*, is it fair they should expect to rank with such as have undergone the toil, the expense, the anxiety inseparable from such qualification?—No: it is not for such as have taken advantage of this remissness in the law to beard those who have conscientiously complied with what the institutions appointed to guard the profession required.

Foreign Medicine.

Treatment by Carbonic Acid Gas in Amenorrhœa and the Uterine Pains which precede and accompany Menstruation.

BY M. LE PROFESSEUR MOJON.

It is well known that females in general, without being attacked by complete amenorrhœa, suffer great pain both immediately before and during menstruation. Various medicaments have been tried in remedy of this suffering, many of which increase it by over excitation of the nerves. M. Mojon proposes, therefore, the use of carbonic acid gas, which he considers an excellent antiphlogistic, in opposition to a great number of medical practitioners, who regard it as a stimulant. Fumigations of this gas may be also advantageously employed in cystitis, ophthalmia, and other local inflammations. This therapeutic agent not only acts on the blood in diminishing its thickness, but also on the solids in relaxing the fibrous system to prostration and torpor.

The gas is disengaged from calcareous carbonate by means of weakened hydro-chlorine acid, and must be conveyed into the vagina through the orifice of an Indian-rubber pipe. These fumigations should be repeated twice a-day before menstruation, and they are found not only to regulate the course, but entirely to relieve the pains which precede, accompany, and follow menstruation. The operation may be hastened with the ordinary apparatus, by the addition of a spigoted bladder, filled with the gas and adjusted over the Indian-rubber pipe, the spigot being turned, a slight pressure on the bladder throws a current of gas into the vagina.

British Hospital Reports.

ST. GEORGE'S HOSPITAL.

Chronic Inflammation, with thickening of the Bladder.

John —, æt. 40, was admitted into this hospital December 1834. He had laboured under a stricture of the urethra for 20 years. When admitted the smallest catgut bougie could not be passed. There was a hard cartilaginous tumour, inclosing a cavity in the perinæum. The urine was abundant, pale, and highly alkaline: it contained a peculiar mucus, resembling a powdery matter, which slightly floated in it, and was intermediate in appearance between mucus and albumen. On applying heat, or adding nitric acid to the urine, its coagulation proved the presence of albumen. There was slight occasional pain in the loins, which, on several occasions, was mitigated or temporarily relieved by a blister.

Instruments were gradually passed through the stricture, but not into the bladder, their point being obstructed by what appeared to

be an abscess in the prostate gland. The latter conjecture was supported by the circumstance, that a great deal of pus was evacuated separately from, and before the urine, the passage of which it occasionally obstructed. The progress was so far calculated to give encouragement, when a train of symptoms was established, which Mr. Hawkins has described with vigour and correctness. We shall venture to extract the description, and the commentary added by the lecturer.

"You have seen Weighell very nearly dying of a sudden increase of renal disease, to a return of which he is still liable at any time. It was in January last that he became low-spirited and out of health; then he had occasional rigors, pain in the back and groins, with more difficulty in making water; then in a few days he had a great quantity of blood in the water, which came suddenly, and continued for two or three days, and before it ceased there came away with the urine a very large quantity of pus, which continued for some little time, and then ceased. While he was at the worst, he lay in a state of listless half stupor, with a quick, feeble, intermitting pulse, and the brown tongue of typhus fever; and he had occasional delirium, and was frequently crying from extreme depression of mind, when not asleep and stupid. These symptoms continued, more or less, for nearly a month, when he began to revive and recover strength; and the symptoms I have mentioned, both local and constitutional, and as connected with the urine, gradually went away, and left him as you now see him.

"Now, what I believe to have happened during this time, was the formation and bursting of an abscess in one kidney, and that probably the right, from an affection of respiration, with pain on that side, which he laboured under for a few days. The discharge of pus from the kidney occurs in three different states. First, a quantity is secreted from the tubular structure of the kidney, and from the infundibula and pelvis, without any cavity like that of an abscess, and while the cortical substance is only inflamed. I have seen this discharge take place suddenly, and to the amount of many ounces daily; so that it seemed almost impossible that it could have happened from the secretion from a mucous surface only; and yet dissection has shown that it did so. 2ndly, you find small quantities of pus partially confined in cysts, consisting of the infundibula and tubes, enlarged and dilated, these cysts communicating with the excretory tubes. Thirdly, you find circumscribed abscesses in the kidney not communicating with the excretory tubes; even these, however, you can often trace to the commencement of the tubes, where a drop or two of pus, confined by adhesive inflammation, becomes the origin of larger collections of matter.

"I judge that Weighell had a circumscribed abscess, from the rigors, and so on, preceding the purulent discharge, and because there was

also a large quantity of blood before the pus, as if the wall of an abscess had been ruptured to give exit to its contents. If I am right on this point, the abscess has since probably filled up."

The treatment employed during this condition of stupor were stimulants of course, a blister to the right side, and a blister, also, to the nape of the neck.

The sequel of the case may be briefly stated. The patient became gradually reduced in strength, emaciation made progress, and about 20th June he was attacked with diarrhoea, attended with much general pain in the abdomen. He died 6th of July, having suffered for a day or two from pain in the head, unaccompanied, however, with actual stupor. During the period that elapsed between the comatose attack and his death, the urethral symptoms continued nearly stationary. The suppuration from the abscess that was thought to exist in the prostate was diminished, and the cartilaginous tumour in the perinaeum had increased. A catheter was occasionally passed.

Dissection.—The cartilaginous tumour in the perinaeum was placed anterior to the stricture, and contained a small abscess, communicating with the urethra. The stricture itself was broad and firm, white in appearance, and situated rather on the left side of the urethra. A catheter of tolerable size could be passed through it. The prostate gland contained an abscess, capable of holding a tablespoonful of pus. At the side of the verumontanum was an opening into the abscess, in which the extremity of the catheter had frequently been involved. The bladder was thickened to the extent of more than half an inch—its muscular fibres were prominent and enlarged, and its mucous membrane dark-coloured, vascular, and folded into numerous little pouches. The ureters, the pelves of the kidneys, especially the left, and the infundibula, were in some degree enlarged, and their mucous membrane was inflamed. The secreting structure of both kidneys was condensed, and of a yellow colour; the left, which was nearly of its natural size, was more vascular and brittle than the right, which was diminished to half its natural bulk.

The chain of consequences resulting from the stricture of the urethra, and the lodgment of urine in the bladder, in the ureters, and in the pelves of the kidneys, are obvious even to the inexperienced pathologist. Perhaps it may be briefly, though not quite correctly, summed in the expression, that chronic inflammation was induced in all the portions of the urinary apparatus affected by the urinary accumulation. The case is interesting, because it informs us what we may expect, and what we should avoid. Mr. Hawkins judiciously dwells upon the circumstance, that pus may be secreted from the mucous membrane of the kidney, in a manner and to a degree which might reasonably warrant the suspicion of a circumscribed abscess in that organ.

WESTMINSTER HOSPITAL.

Anomalous Eruption.

TIMOTHY HOLLAND, ætät 33, a native of Ireland, was admitted, Dec. 9, 1834, under Mr. Guthrie, into Burdett Ward. He became an in-patient of the hospital, on account of a squamous eruption affecting the face and extremities, more especially the left thigh and leg, the body being perfectly free. The patches on the extremities are completely circular, varying in size from a half-crown piece to near that of the palm of the hand, are situated principally on the outside of the limb, considerably elevated above the surface, with a slight areola of inflammation. Those on the face do not assume any regular form, nor do they affect any particular part. His health is much affected; he appears to be of the cachectic habit of body, much debilitated, with a small and weak pulse; the body exhales a most unpleasant acid odour; features indicative of anxiety and depression, and he complains of constant and severe pain in the diseased parts. He is about the middle height, of the leuco-phlegmatic temperament, not married.

The account he gives of himself is as follows:—He has never had syphilis or gonorrhœa, and he cannot assign any cause for the complaint. It first showed itself when he was thirteen years old, and he generally but not always has an attack once in the year. It first invaded the extremities, but afterwards affected the face; he has never had any spots on the body, nor, until the last attack, on any other part but those already mentioned; during the illness previous to that under which he at present labours, one or two vesicles appeared on the prepuce, and which scaled like the disease of the extremities. It is difficult to ascertain from him whether the complaint commenced by a vesicle, pustule, or tubercle, as he at different times describes the whole three as the primary affection: it would appear, however, to be at first vesicular. His present complaint commenced six weeks ago.

Previous to an attack the general health is disordered for a week or two, marked by inappetence, emaciation, general debility and listlessness, derangement of the stomach and bowels, furred tongue, &c. His history gives no evidence of a syphilitic origin, which the circular appearance of the disease on the extremities would appear to indicate. He has been treated for this affection in the Cork Hospital, at Guy's, at the Charles-street Dispensary, and elsewhere; in one place salivation has been caused, mild antiphlogistic treatment has been adopted in another, and each with the effect of removing the disease, but not of preventing a relapse.

He was ordered a warm bath every night, poultices to the extremities, and the diaphoretic mixture internally.

The poultices removed the scabs, when large circular ulcers, not extending deeper than the integuments, and of a perfectly regular surface,

were exposed; the inflammatory areola encircling these ulcers was larger than before. Some of these were ordered to be dressed with an ointment containing ʒj. of the dregs of yellow wash to ʒj. of simple cerate; this application proved too irritating, even when diminished one-half; the poultices were, therefore, to be resumed, those which had been poulticed throughout looking better. A point worthy of notice was the manner in which these ulcers enlarged; an inflammatory areola preceded, then the cuticle became raised, with a little serum deposited between it and the cutis, and, finally, ulceration attacked the part, while points of cicatrisation might be seen in the centre.

Dry lint was afterwards applied to these ulcers, the cupri sulphas being occasionally had recourse to; the general health improved somewhat, the appetite being greater, the pulse acquiring more volume and power, and the man gaining strength and flesh, but still having the cachectic cast of countenance. Under this plan the ulcers healed, and some of the scabs on the face fell, leaving a red, but smooth and unbroken surface.

Jan. 31st. The scabs on the face are more numerous than they were, but there are several spots where they have been spontaneously detached; the extremities are clear.—Ordered to continue the warm bath, and to omit the diaphoretic mixture.

R. Extr. sarsæ, ʒj.

Decoct. sarsæ, c. O iss., solve.—Sumat æger 4tam partem bis in die.

Feb. 5th. Has commenced taking the sarsaparilla.

14th. He says that he is nearly free from pain, and has been much easier for some time; he experienced relief soon after he commenced the sarsaparilla; the scabs have separated from almost every part of the face, leaving an unbroken surface beneath, quite healthy, but rather reddish. His general health is much improved, and his spirits proportionally raised. The outer half of each supercilium has been destroyed by the disease.

21st. Has continued to improve since the last report; the parts from which the scabs have been detached are perfectly sound, and there are very few any where.

March 1st. Is quite free from any traces of his complaint; is getting fat and strong; has continued to take the sarsaparilla, and to use a warm bath nightly.—Discharged on the 17th.

This case is headed "*anomalous eruption*," inasmuch as it remained doubtful to what cause it should be attributed, and also its real nature was not satisfactorily settled. Some of the surgeons regarded it as pure syphilis, an opinion which the circular character of the sores seemed to support. Several medical gentlemen of the sister kingdom who saw the case, considered it to be of the same nature with a disease peculiar to, and common in, Ireland, called *sivens*, dependent on a cachectic habit of body.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, March 19th, 1835:—Robert Geo. Higgins, Newport, Salop; George Augustus Place, Hampteston, Dorset; Wm. Whitcombe, Cleobury, Mortimer; Henry Rich. Gawin Tripe, Plymouth; William Mackie, Oundle.

MISCELLANY OF FACTS.

Curious Instance of Gratitude.—The Treasurer of the County of Antrim Infirmary has received, for the use of that institution, the sum of £20, with the following letter, from William Stewart, Esq. M.D.:—"My dear Sir,—I have great pleasure in forwarding to you, as treasurer, a sum of money, presented to me for the funds of the County of Antrim Infirmary, under the following circumstances. On Sunday last, my servant told me that a man and woman, who were in the hall, wished to speak to me. On going down, they appeared of that class of people who seek for gratuitous medical advice. The female then said, I wish, sir, to talk to you in private. On my going into the parlour, she asked me if I recollected having ever seen her. I told her not. She then spoke to the following effect. Upwards of sixteen years since I was a patient in the infirmary, for extensive ulcers on my leg, and asked you if you thought they could be cured and you said it was quite doubtful. In despair I went to the summer house in the garden, fell on my knees, prayed to God to bless your endeavours, and vowed to him, if I got well, and if ever it were in my power, I would give something to the infirmary. My leg was healed, and is now quite well, and I never forgot my vow. About six years since I had the sum I am now going to give you made up, but was obliged to use it for other purposes. I am now, thank God, enabled to fulfil my promise, and beg of you to give these twenty pounds to the Treasurer, and am sorry it will only produce one pound a-year. On my pointing out to her that, from her appearance, I suspected she could not afford to give so much, she replied that she could do it, that she kept a small shop, and that her family could support themselves by their trades; and said, I now feel satisfied in having fulfilled my vow to God.—I am sorry to state there are few persons that would have been so thoughtful to the institution. I remain, &c.

"Wm. Stewart, Surgeon, &c.

"Lisburn, March 6.

"To Edw. Johnson, Esq., Ballymacash."

Mr. H. Deny is, we understand, during the ensuing summer, about to give a Course of Lectures on the Causes and Treatment of Diseases of the Skin in Children. This is the first time this has been made a special subject in this country, and heartily do we wish Mr. Deny success in his undertaking.

His Grace the Duke of Wellington has consented to become President of the Eastern Dispensary, Great Alie-street, Goodman's-fields, and accompanied his acceptance with a munificent donation of £100 toward the funds of the institution.

APPOINTMENTS.

Military.—Assistant-Surgeon A. Shanks, M.D., from the 82nd reg. to be surgeon of the 55th Foot, vice Campbell, appointed to the 93rd reg. Surg. J. Campbell, M.D., from the 55th reg. to be surgeon of the 93rd Foot, vice E. Bush, who retires upon half-pay. The half-pay of Assistant-Surg. A. Lusignan, of the Canadian Voltigeurs, has been cancelled from the 1st March, 1835, he having accepted a commuted allowance for his commission. Mr. Seaton, surgeon of the Royal Artillery at Portsmouth, ordered on the Medical Staff in Canada.

DEATHS.

Mr. Benjamin Carr, of Knaresborough, surgeon, in a fit of apoplexy while taking tea. Dr. Theodore Waterhouse, of Liverpool, one of the physicians to the Northern Hospital in that town. In Edinburgh, Mr. Samuel Williamson, formerly of the East India Company's medical service. Mr. Henry Garbett, of Hereford, surgeon. At Charlsetown, Nevis, Mr. Samuel Fitzherbert Bowden, surgeon, formerly of Bath. Mr. James Ackell, of Cheltenham, surgeon. Mr. John Turner, surgeon, of Shelly Bank, near Huddersfield.

WEEKLY BILL OF MORTALITY.

London, Tuesday, March 24th, 1835.

Increase in Burials reported this week, 99.

CORRESPONDENTS.

In answer to the inquiry of *Aristides*, we state that, both in our general observations and in our strictures on books received, we shall avoid zero and the boiling point, and neither have praised, nor shall praise, bad works, nor condemn good ones.

X. X.—His extract shall be inserted as soon as we have time to review the whole affair; our press of matter will prevent that taking place for some time.

Cantator.—The allusion to certain students in King's College, contained in his poem, we cannot in the present state of the singers' professional career notice; we intend hearing them on the coming Sunday, and if their execution be no better than the poetic strains of our correspondent, we may be tempted to give them, in our ensuing, a note or two on our double bass, which, although it may not harmonise with their treble, may perhaps appear to them somewhat counter.

Inquirer.—The child, if expelled with the membranes unbroken and placenta *en masse*, cannot in general preserve vitality longer than from two to three minutes.

Veritas.—The lectures of Dr. Roots and Elliotson will appear.

Cadwalader.—"Quain's Anatomy."

As to the practice of medicine, the Lectures of Dr. Stokes in this Journal far surpass any work published on that subject, except Dr. Mason Good's practice. The Surgical Dictionary of Samuel Cooper is a good substitute; his lectures, also given by us, are a good adjunct.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

At the Meath Hospital during the Session of 1834-5.

LECTURE V.

Case of suspected Thoracic Aneurism—Edema of left Arm and left Side of the Face—Probable Cause of—Relations of the left Vena Innominate to the Arch of the Aorta—Reasons for concluding that the Symptoms are produced by a solid Tumour—Its Effects explained—Another remarkable Case of Thoracic Tumour related—Case of violent and extensive Pulsation of the Heart depending on Cerebral Disease—Laennec's Error concerning the Indications for Bleeding—Case illustrative of—Use of Digitalis in such Cases—Case of Asthma, and treatment—St. John Long's Liniment—Dropsy treated by Opium—Acupuncture in Anasarca.

GENTLEMEN,—The object of clinical instruction being the study of diseases—their nature and their treatment, it is our duty to apply that study in the manner most likely to encourage the accumulation of practical knowledge. In accordance with this view, and in order to prepare you for the various emergencies that may hereafter demand the application of that knowledge, I shall proceed to select, from the cases at present in the house, such as, from their singularity, interest, or importance, seem to claim something more than a mere passing notice.

A man named James Byrne, who lies next the door in the chronic ward, and has been supposed to labour under aneurism of the thoracic aorta, leaves the hospital to-day. It is very probable, however, that he will hereafter be forced to return; for, whatever be the nature of his disease, it is incurable, and depends on some profound organic lesion. I would advise any gentleman, who has not attended to this very obscure case before, to take the opportunity of making an accurate examination of the patient during the short time he remains in the hospital.

While the phenomena of this case are still fresh in our minds, let us briefly discuss the question, whether this man really has aneurism of the thoracic aorta, and inquire whether there may not be some other cause to which his symptoms might be attributed with a more reasonable degree of probability. He was admitted on the 23rd of October, 1834, and had been in the hospital before for a considerable time. He states, that eighteen months previously to his last admission he was exposed to wet and cold, which produced a feverish attack, with symptoms of local inflammation in the lung, manifested by cough and difficulty of breathing. These were soon afterwards followed by dropsical swelling, and he applied at this hospital for relief. After remaining under treatment for about two months he began to improve and left the hospital, as he states, quite relieved. He enjoyed tolerably good health, and continued to work at his trade as a bricklayer until about five weeks before his last admission, when he was again attacked with cough and difficulty of breathing, accompanied by œdema of the left side of the chest and left arm. On examining him after his admission the following phenomena were observed:—The left side of the face and neck was slightly œdematous; the left external jugular vein with its immediate branches engorged and very prominent; the left arm and left side of the chest œdematous, and pitting on pressure; no affection of the bronchial mucous membrane, or parenchyma of the lungs, sufficient to account for the cough, can be detected by auscultation. Considerable dulness over the situation of the heart, and extending upwards over the sternal region on the left side; the right sternal region sounds clear and natural. The heart has not been removed from its normal situation; its pulsations can be felt over the ordinary extent, and no more, and they communicate a natural impulse to the finger. On applying the stethoscope over the heart its sounds were found to be regular and natural, but on placing it higher up, over that part of the sternal region which was dull on percussion, a loud *bruit de râpe* was heard.

Let us analyse these symptoms. In the first place, we found the anasarcaous swelling

occupying the left side of the chest and the corresponding arm, and in a slight degree the left side of the neck and face, accompanied by a turgid state of the jugular vein. Now, you may lay it down as a general rule, that where one side of the chest and the corresponding upper extremity is affected by anasarca, it proceeds from some cause residing in the chest. I have told you before that in all cases of dropsy, whether acute or chronic, whether accompanied by ascites or not, *when anasarcaous swelling appears in the trunk and upper extremities before it is observed in the abdomen or lower extremities, the dropsy in general is inflammatory, or, when not so and chronic, it proceeds from disease of some of the thoracic viscera*, and it is in the chest alone that we are to look for its cause and origin. Now, applying this rule to the present case, we are led to inquire, what is it that by pressing on the veins within the chest gives rise to engorgement of the superficial vessels on the left side of the neck, and to anasarcaous swelling of the left arm and left side of the chest. The pressure must, in our patient, be applied to a portion of the venous system, which carries blood from the left side of the head and the left upper extremity; in short, it must be applied to the great vein formed by the junction of the left subclavian and left jugulars. Now, this left *vena innominata sive vena brachio-cephalica* differs considerably from its fellow on the right side, which is very short, and nearly vertical in direction. The vein on the left side is three times longer, and directed transversely to the right, inclining, at the same time, downwards. It crosses behind the first bone of the sternum, lying in front of the three primary branches given off from the transverse portion of the arch of the aorta. You perceive, therefore, gentlemen, that it lies in a position most convenient to receive pressure in consequence of aneurism in any of these great vessels. This vein receives, before joining the cava, the internal mammary vein of the left side; you understand now why anything pressing on it is apt to produce engorgement of the superficial veins on the left side of the chest and trunk, together with œdema of these parts.

That we are not to look for the cause of the disease in the heart itself appears from various circumstances. The situation of that organ is not changed; its beating can be felt only over the usual extent of surface; it communicates a natural impulse to the finger; and when examined with the stethoscope its sounds are discovered to be normal and regular. Neither can we attribute the disease to any affection of the mucous lining or parenchyma of the lung; the only morbid sounds which can be detected in the respiratory organs being a few slight bronchial râles.

Now, it is sufficiently obvious, gentlemen, that the situation of the part which sounds dull on percussion would suggest the idea of aneurismal dilatation of the arch of the aorta,

or some of its immediate branches. But had dulness over so large a space of the chest, embracing nearly the whole left sternal region, been produced by aneurism of the aorta, or any of its branches, it is evident that the aneurismal sac must be very large. Where an aneurism gives rise to extensive dulness of the chest, you may be always certain that it has arrived at a very considerable size; for the dulness is caused by the immediate contiguity of the aneurismal sac to the parietes of the chest, and hence the dulness is always in proportion to the amount of lung displaced. When you applied your hand over the sac, in such a case as that which we are now considering, where the aneurism was of large size and closely applied to the parietes of the thorax, you would feel a very remarkable pulsation; your hand would be, as it were, lifted from the chest by each impulse communicated to the sac, and you would have palpable, unequivocal evidence of the cause of the dulness on percussion. Now, in the case before us, there was no such pulsation observed, whether we examined him while lying quietly in bed, or after he had walked briskly about for some time so as to excite the action of the heart and arterial system. Again, aneurismal sacs, as you are all aware of, before they produce extensive dulness of any portion of the parietes of the chest, point, as it were, in some particular situation, becoming distinctly prominent, and producing an eccentric motion around them, in consequence of the thoracic parietes being absorbed, or yielding at the point of greatest pressure.

From these circumstances considerable doubts have arisen in my mind as to the cause of this man's symptoms being connected with aneurismal disease of the great vessels of the thorax. I am rather inclined to attribute the *bruit de râpe* and dulness of sound on percussion to a lesion of a different character. Let us suppose that in this case a tumour has been developed in the cellular or glandular substances, situated in or towards the left side of the chest, occupying the anterior mediastinum, pushing back the lung and pressing on the large vessels connected with the base of the heart; what are the phenomena it would naturally present? First, we should have dulness of sound on percussion, corresponding in extent with that portion of the chest to which the tumour was applied; secondly, we should have *bruit de soufflet*, and probably *bruit de râpe*, in consequence of the pressure of the tumour on the aorta; thirdly, a tumour in this situation would necessarily compress some of the larger bronchial tubes, and thus give rise to cough and dyspœa. If a tumour presses on the trachea, or one of the larger bronchial tubes, why does it produce pulmonary irritation? Not by mere pressure on the part, for the pressure is applied so gradually, and with such a broad surface, that its effects could be scarcely felt; and it might go on to produce complete obliteration of the tube with-

out giving rise to any inflammation, if its action were limited exclusively to the part compressed. But it strangles as it were that portion of lung to which the tube belongs; a certain portion of a large bronchial tube is considerably narrowed by the pressure of the tumour, the free entrance and exit of air are impeded, and consequently that portion of the lung, which may be very large, is greatly deranged in its functions. Hence arises that sensation of distress, termed dyspnoea. Again, as soon as the free ingress and egress of air are prevented, we have not only the occurrence of dyspnoea, but also other effects equally referable to the same cause; the blood circulating through that part of the pulmonary tissue is imperfectly aerated and does not undergo the necessary change; the secretions and exhalations from that part are altered and unnatural, and consequently it becomes engorged, giving rise to irritation, cough, and expectoration. To understand this aright, you should bear in mind that this portion of the lung undergoes the same changes that the whole of the lungs undergoes in persons who are asphyxiated; that is, it becomes gorged with blood, for the moment that the black venous blood which is carried into the pulmonary tissue from the right side of the heart ceases to be properly aerated, that moment it stagnates in the lung, and soon renders it engorged. This is precisely the state of lungs which occur in the posterior portions of those organs in persons who die a lingering death, and which has most absurdly been termed the pneumonia of the dying.

But, to return to this man's case, I am inclined to think that the symptoms here present may with more colour of probability be attributed to the presence of a solid tumour developed within the chest, the nature of which I can only guess at, and that it is situated in the anterior mediastinum close to the origin of the aorta. Some of these tumours which have been discovered in the chest are of an adipose nature, some of them resemble the cerebral substance in colour and consistence, and others are like the steatomatous tumours formed in other parts of the body.

A few months ago, Surgeon Blackley was consulted about a young gentleman who had been gradually attacked with symptoms of pulmonary irritation, cough, and difficulty of breathing. The disease was supposed by some to be consumption, and a physician who had been in attendance thought it depended chiefly on derangement of the stomach. Mr. Blackley had his doubts with respect to both of these opinions and requested of me to visit and examine the patient. I could not detect any râles indicating the existence of tubercles, but over a large portion of the chest, and nearly corresponding with that part which sounds morbidly in the patient Byrne, there was dullness on percussion, the young gentleman had fits of cough and dyspnoea, and now and then difficulty of swallowing; a *bruit de soufflet* could be heard over the dull portion of the

chest, but the sounds and impulse of the heart were regular and natural. I expressed a very doubtful opinion of the case, but at the same time stated my belief that the case was not one of tubercular phthisis, of empyema, or of pneumonia, and I also said that it did not seem to be produced by disease of the heart itself. I dwelt especially on the existence of *bruit de soufflet* in the region which was dull on percussion, and which was somewhat removed from the heart, and which, from its situation, I interpreted as indicating something pressing either the arch of the aorta or some of its branches. I was not able to detect pulsation or any other symptom of aneurism, and consequently professed myself unable to say what that something was. The result proved that, although the true cause of the disease did not occur to me, I had nevertheless approached the discovery as nearly as could be done without actually making it; for, soon after this, the young gentleman died, and on opening the chest a large tumour of a steatomatous character was discovered pressing on the divisions of the trachea, of the aorta, and on the œsophagus. Another case of the same kind was published some time ago in the *Dublin Medical Journal*. We are, I believe, still in the infancy of diagnosis, so far as regards tumours developed in the chest, producing anomalous symptoms, and giving rise to suspicions of aneurismal or tubercular disease. With respect to the patient Byrne, I am inclined to think that the morbid phenomena are referable to a tumour of this description, and I ground my diagnosis chiefly on the absence of pulsation, which should be distinctly present if the dullness on percussion here observably depended on the proximity of an aneurismal sac to the parietes of the thorax.

As I am speaking of pulsation, permit me to observe that in some cases where there is no actual disease present, the pulsations of the heart are visible over a very large extent of surface, so as to convey the impression that aneurismal dilatation exists. Of this I have lately seen a very remarkable example. In a case which I saw this week with Mr. Cusack, the patient's heart could be observed beating violently over the whole chest, and Mr. Cusack, when he laid his hand on the patient's chest, said he could not divest himself of the idea that there was some unnatural condition of the heart and great vessels. Now the violence of the heart's action in this case depended on disease of the brain. In some inflammatory or congestive diseases of the brain with a tendency to coma the heart labours intensely, its pulsations are quite awful, and it seems as if it were about to burst through the parietes of the chest. Again, this extraordinary action of the heart occurring in cerebral disease is almost invariably accompanied by a hard bounding pulse. I mention these circumstances for the purpose of putting you on your guard, and that you should not in such cases allow yourselves to be deceived and

suppose that the symptoms are to be met in every instance by copious blood-letting. Some cases of this description will bear depletion well, others will not. You know it was a maxim of Laennec's, that in bleeding we are to be guided more by the strength of the heart's action than by that of the pulse. I have already shown that this test does not always hold good. You recollect the patient who was under treatment here some time ago with violent action of the heart and a hard bounding pulse. This patient, a strong healthy man, had just disembarked after a rough passage from Liverpool, during which he vomited much, and suffered intensely from headach, which he ascribed to the violence of retching. Walking along the quay he was suddenly attacked with hemiplegia, and was immediately brought into hospital, where he was bled and purged. Next day we found him still hemiplegic, and complaining of violent pain in the head. Active antiphlogistic treatment was used, but on the third day he became comatose, and was convulsed in the limbs of the healthy side. His face was flushed, his temporal arteries were dilated and pulsated violently, and his pulse was hard, while the heart pulsated with great strength. This attack came on during our visit, and I ordered a vein to be opened immediately. The blood flowed freely. When about fourteen ounces were taken the pulse suddenly flagged and grew extremely weak, and never again rose. He died in about two hours, and an ignorant person would have ascribed his death to the bleeding. On examination, sixteen hours after death, we found extensive puriform effusion on the surface of the brain, together with a large clot of blood and surrounding ramollissement. This was a very remarkable case, and conveyed a very important lesson, teaching us not to be too much led away by the violence of the heart's action; for I have no doubt that here the use of the lancet shortened the man's life. Had such a case as this occurred to any of you in private practice, it would be almost fatal to your reputation. Here we have a patient with his face flushed, his skin hot, his temporal arteries throbbing violently, and his pulse feeling like a piece of whipcord; he is blooded, and up to a certain point the pulse remains firm; he then begins to sink rapidly, and expires in two or three hours. Bear in mind then, that a state of the system may exist, in which the heart's action is intense, and the pulse hard and bounding, and yet where bleeding to any amount will be badly borne. Such cases are generally connected with inflammation of the brain accompanied by a tendency to coma. Here you must bleed with great caution, let the quantity you take away be moderate, and rather rely upon large relays of leeches and strong purgatives for removing the cerebral symptoms. You may afterwards endeavour to moderate the heart's action by the use of digitalis and opium; a grain of the former, and one-twelfth of a grain of the latter, made into

a pill with some extract of hops, may be given every second hour, until it begins to produce some effect on the heart's action, when it may be either discontinued or given at longer intervals, as the circumstances of the case require. Where, after bleeding and other antiphlogistic measures, the pulse continues high and the action of the heart violent, I can recommend digitalis very strongly, and the small portion of opium here combined with it can do no harm. Combined in small quantities with digitalis, opium does not produce any tendency to determination to the head, and it prevents the digitalis from sickening the stomach. I have frequently employed it, and found great benefit from its exhibition. I may observe that when you are anxious to secure the full sedative effects of digitalis on the heart and pulse, you must give it in large doses. In small quantities it does not act well, and seems rather to produce a tendency to excitement of the heart.

There is another patient about to leave the hospital to-day, on whose case I wish to make some observations. This young man, whom you have seen lying in the chronic ward in the bed next but one to Byrne's, caught cold about seven or eight months ago, followed by cough, wheezing, and dyspnoea, which, after a month or six weeks, subsided. About two months before he came into the hospital, he renewed his cold, and with it the cough and dyspnoea returned. On his admission he complained of difficulty of breathing, which attacked him every night; he went to bed well, and slept tranquilly for two or three hours, and then was awakened by pain and sense of tightness in his chest with great dyspnoea. When the paroxysm came on, it compelled him to get up and walk about the room gasping for breath, and, after continuing for two or three hours, with great dyspnoea, wheezing, anxiety, and cough, went off with free expectoration and sweating. As soon as the sweating and expectoration appeared, he lay down without any inconvenience, and slept quietly until morning. The only additional symptom he complained of was palpitation of the heart, which sometimes affected him when employed at hard labour. On examining the lungs there was nothing found except a few bronchitic râles. The heart was normal in its action, and no morbid sound could be detected by the stethoscope. In addition to this, you will recollect that the man was in the prime of life, had a full and well-formed chest, a quiet pulse, regular bowels, and a good appetite.

Here you perceive a man from repeated colds gets chronic irritation of the bronchial tubes, and this induces asthmatic paroxysms, which come on, as is usual in such cases, at a certain hour of the night. It was plain, therefore, that he was labouring under a well marked form of asthma, a disease which, in its pure and simple state, is seldom met with in hospitals, being generally observed in connexion with disease of the heart, or long continued bron-

chitis in old persons. Chronic bronchitis is one of the most common causes of asthma, indeed, you will scarcely ever meet a patient who has been subject to chronic irritation of the bronchial tubes, who does not also labour under more or less asthmatic dyspnoea. The disease is generally met with in persons advanced in life, and who have suffered from repeated attacks of bronchitis; it is not usual to find it in so young a man as this patient, and presenting as he does such very slight symptoms of derangement of the bronchial mucous membrane.

This case exhibits a remarkable proof of what may be done by simple means in relieving an urgent disease. The man was, with the exception of asthma, in good health; his bowels were regular, his appetite good, his pulse tranquil, and the signs of pulmonary irritation trifling. There was no necessity then for administering remedies to improve the tone of the digestive organs, nor were we authorised to use the lancet or apply leeches. I therefore confined my attention to two points, the application of irritants to the neck and chest externally, and the internal use of remedies calculated to relieve bronchial irritation. I ordered him to rub the nape and sides of the neck, and the fore part of the chest, with a liniment composed of strong acetic acid, ℥ ss, spirit of turpentine, ℥ iij., rose water, ℥ iiss, essential oil of lemons a few drops, and yolk of egg in sufficient quantity to suspend the turpentine. This liniment is an imitation of the celebrated liniment of St. John Long. I gave a bottle of the real liniment to Dr. Apjohn to analyse, and he thinks it consists of acetic acid, spirit of turpentine, and two animal matters, one containing azote, the other not; the latter probably some species of fat, probably goose-grease. Now this fat did not exist in St. John Long's liniment in the form of soap, it was evidently some kind of fatty matter blended with water, probably by means of trituration with yolk of egg. The active ingredients are spirits of turpentine and strong acetic acid. This liniment should be applied by means of a sponge. It acts as a rubefacient, and generally induces an eruption of small pimples after a few applications. The spirit of turpentine must be well mixed with the water (which ought to be added to it gradually) by means of yolk of egg, before the acetic acid is added.

With this liniment our patient was desired to rub the fore part of the chest, and the nape and sides of the neck. It was applied to the chest with the view of relieving the bronchial irritation, and we ordered it to be rubbed over the nape of the neck, along the course of the cervical portion of the spinal marrow, and over the sides of the neck along the course of the pneumo-gastric nerve, because all the organs to which the latter nerve is distributed are evidently affected in cases of spasmodic asthma. Thus a paroxysm of asthma is not only attended with increased action of the

heart, dyspnoea, and hurried breathing, but also with marked derangement of the stomach, particularly towards the termination of the fit, when the patient generally has a feeling of uneasiness in the stomach, with flatulence and a sense of fulness, induced probably by the derangement of circulation in the lung. You are aware of the close sympathy which exists between the stomach and lungs, and you must have been struck with the fact, that stimulant and irritating remedies applied to the epigastrium often relieve affections of the lung more completely than when applied to the chest. Thus in using the tartar emetic ointment for the relief of whooping-cough, it has been found to act most beneficially when applied over the region of the stomach, and the same thing may be said of Roche's embrocation, which does more good when rubbed over the spine or epigastrium, than when applied to the parietes of the thorax. On these principles, I ordered the counter-irritation to be applied over the course of the cervico-spinal and pneumogastric nerves, over the chest, and subsequently over the stomach.

This liniment in a very short time produces redness and heat of the parts to which it is applied, and it is more than probable that its effects are not limited to temporary rubefacence, but that it also acts on the nervous system. We have innumerable proofs that turpentine exercises a special influence over the nervous system, and we know that it is rapidly absorbed even without the aid of friction. I fear, however, that we shall never be able to confer on our liniment all the wonderful properties attributed to that of St. John Long's. You know it has been asserted that St. John Long's liniment never reddened the skin, except over the exact spot where disease was situated. I was assured by a young lady who used this liniment, that she rubbed it all over the chest, and that it produced no discolouration of skin, except in two spots where she felt pain. She at first mentioned but one spot which was painful, but St. John Long, having applied the liniment himself, told her she had deceived him, and that there was pain in another spot. It had other effects equally miraculous. An eminent Dublin lawyer declared that it drew nearly a pint of water from his head, and Lord Ingestre testified that it extracted quicksilver from his brain! These and other wonderful stories, told by several persons of distinction with a full belief in their authenticity, furnish a useful lesson to mankind, showing that gross credulity is not confined exclusively to the poor and the ignorant, but may be found among the highest classes of society. It is a singular fact also, and illustrative of the tendency which exists in human nature to deceive and be deceived, that notwithstanding the repeated failure and even fatal effects of St. John Long's applications, many persons still regard his opinions as oracular, and look upon

his remedies as inestimable discoveries. When I mentioned to the gentleman who brought me the bottle of liniment, that St. John Long himself died of phthisis, and brought this forward as a strong argument against the infallible efficacy of his remedies, he said that this very circumstance was one of the most remarkable proofs of his sagacity, for St. John Long had always maintained that the liniment was not suited to his own case, and that there was something in his constitution which neutralised its good effects; and so it happened, for when he applied the liniment to his skin, it did not produce the red spots which usually resulted from its application in other persons. In fact, such was the credulity of St. John Long's patients, that his death passed among them as the strongest proof of the infallibility of his medicines. Indeed he is considered by many of our nobility as a sort of medical martyr, who, having sacrificed life in the accomplishment of his mission, rising from earth, let his prophetic mantle fall on the highest bidder!

But to return to our patient. In this case the liniment did a great deal of good, but it was not the only means we employed. We observed that the asthmatic paroxysm came on every night, continued for two or three hours, and then went off with free expectoration and sweating. In order to prevent this, we gave him a draught, which he was to take when awakened by the pain and sense of tightness in his chest. He took this, and it had the effect of arresting the paroxysms, so that he no longer found it necessary to leave his bed. That this remedy had succeeded in averting the disease was plain from the following circumstance:—one day the clinical clerk had omitted to repeat his draught, and he consequently got no medicine; on that night the asthmatic paroxysm returned and went through its usual course as before. This draught was very simple, being composed of half a drachm of tincture of hyoscyamus, half a drachm of vinegar of squills, and the same quantity of ipecacuanha wine in an ounce of camphor mixture. It is scarcely necessary for me to explain the nature of the ingredients. The tincture of hyoscyamus possesses narcotic and antispasmodic properties, and ipecacuanha and squill are known to have great efficacy in disease of the bronchial mucous membrane, being both promoters of expectoration, and the latter also acting on the urinary organs. Without, however, attempting to explain the precise mode in which each of these ingredients acted, it will be sufficient to state that the combination had a beneficial effect, and checked the asthmatic paroxysms. We persevered in using it, as well as the liniment, until all tendency to asthma had disappeared, and the normal state of the function of respiration became perfectly re-established.

There is in the male chronic ward a patient named Garret Kane, to whose case I shall for

a few moments draw your attention. This man is about forty-five, and, like most of his countrymen who have been addicted to whiskey, he is beginning to show the fatal effects of intemperance. He has been ill for several months before he came into the hospital, and is at present labouring under general anasarca affecting the chest, upper and lower extremities, accompanied by an accumulation of fluid, but not very extensive, in the cavity of the peritoneum. I do not intend here to enter into the general pathology of dropsy, or to inquire what was its origin in this instance; I shall confine myself to an explanation of the reasons which have induced me to select the plan of treatment I have adopted. In the first place, it is a case of chronic dropsy; secondly, it is unattended by fever; thirdly, it is a case in which mercury has been used with some temporary relief, but the disease returned afterwards in a worse form; lastly, it is dropsy accompanied by obstinate diarrhoea, and therefore contra-indicating the use of purgatives or even of diuretics, for you are aware that the whole class of diuretic medicines acts more or less on the intestinal canal. I may mention here acetate and nitrate of potash, turpentine, colchicum, squill, and many other remedies of the same kind. All diuretics act either as purgatives, or they have a stimulant and irritating effect on the bowels. This patient has bowel complaint, and therefore we are prevented from giving diuretics, or purgatives; and the absence of inflammatory symptoms precludes the employment of the lancet or cupping-glasses. You perceive that our field for practice is extremely limited; we dare not bleed, cup, purge, give mercury, or diuretics; the nature of the case contra-indicates the use of all these remedies, and hence we are deprived of the power of using the most energetic agents employed in the treatment of dropsy. What then is to be done? Having observed that the man's appetite and thirst are very great, and that his urine contains a large quantity of albumen, that he has no fever and no symptoms of local inflammation, I decided at once on trying the efficacy of Dover's powder in doses of a scruple in the day, divided into four pills, and gradually increased until it amounts to half a drachm, or two scruples, in the twenty-four hours. A species of analogy exists between cases of this kind and cases of diabetes; in both there is the same tendency in the blood to part with its watery constituents, in both the same inordinate thirst and craving appetite are observed, and in both there is the same deposition of animal matter in the urine. The principal difference between them is, that in one case the watery fluid is effused into the cellular substance and peritoneal cavity, while in the other it is eliminated from the system through the medium of the kidneys. It was this analogy which led me to adopt Dover's powder in the treatment of this man's case. Last year we had a patient here under treat-

ment who was dropsical, and at the same time passed five quarts of urine daily; before I had recourse to the ordinary treatment for dropsy, I determined to try the use of Dover's powder. The disease yielded rapidly to this plan of treatment, and the man left hospital quite relieved.

In the patient Kane a small sore has formed on one of the lower extremities, perforating the skin and cellular substance to the depth of two or three lines; through this aperture a great deal of the anasarous fluid has drained, and still continues to flow off. This is a very fortunate circumstance, as it will tend to prevent any excessive accumulation in the cellular membrane. Previous to its occurrence I had ordered the scrotum and prepuce, which were enormously distended, to be punctured with a needle. The best mode of doing this is to prick the part quickly, so as to give as little pain as possible, the point of the needle should merely penetrate the true skin, the punctures should vary in number from twenty to fifty or sixty, according to the size of the part and the extent of the effusion, and they should be at least half an inch asunder. By observing these rules you will succeed in evacuating the water without running the risk of exciting erysipelas, which in such cases frequently leads to disastrous consequences. Puncturing with a lancet is not so good as with a needle, it is much more apt to excite irritation in the parts, and thus lead to the supervention of erysipelatous inflammation. The judicious application of acupuncture in cases of chronic dropsy often accomplishes a great deal, for when the external anasarous œdema is thus drained away, the fluid in the peritoneal cavity is more rapidly absorbed; in some cases, indeed, the good effects of external drainage on the ascites are so rapid, that we are almost tempted to believe that some direct communication may exist between the subcutaneous tissue and the apparently shut sac of the peritoneum. Be this as it may, the good effects in some cases are as decisive as if such a communication existed. This phenomenon countenances the hypothesis of the possibility of fluids percolating through lining membranes.

Note.—In the foregoing lecture I have adverted to a subject not hitherto sufficiently considered by pathologists, viz. the immediate effects produced in the bronchial tubes and pulmonary tissue when an internal tumour presses on one of the bronchi. The result is a certain degree of cough, expectoration, and dyspœa. In some cases the bronchial inflammation thus produced may go on to actual ulceration, which authors have been too much disposed to regard as being mechanically produced by the local irritation of pressure. Professor Albers, of Bonn, cites one case in which a scirrhous tumour of the œsophagus produced ulceration of the neighbouring compressed bronchus; but he says nothing of the manner in which this effect was accomplished. In some cases, no doubt, inflammation may be

propagated from the morbid growth, but in the tumours I speak of no evidence of inflammation existed. Professor Albers's observations on this subject may be seen in his paper on Widening of the Pulmonary Artery, *Rust's Magazin für die gesammte Heilkunde*, 42 Band, 1 Heft, p. 177.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXV.

Forceps—Turning.

GENTLEMEN,—At my last lecture I endeavoured to make you acquainted with some of the points of interest connected with the history of the forceps; I also told you the circumstances under which their application is indicated; it now remains for me to describe the manner in which they should be applied, and the rules which are to guide you in performing this operation. In doing so I shall confine myself to a few short practical directions, which I have found to be useful to myself at the bedside, and which will not only give you a simple view of this operation, but will materially assist you in performing it. The circumstances under which it is, *ceteris paribus*, most easy to apply the forceps, are where the head is at the inferior aperture of the pelvis, near to, or already touching, the perineum; in this case the straight forceps are sufficient for the purpose, and I shall therefore speak of their application first. Having previously ascertained that the bladder and rectum of your patient are evacuated, and placed her upon the left side, with the nates as near as possible to the edge of the bed, the first point to be considered is, which of the two blades is to be selected; in doing this recollect the rule, *to introduce that blade first, the lock of which looks forwards*, this will be sometimes the upper and sometimes the lower blade, according as the forceps are made; if you do not attend to this point you will be liable to find that, on passing the second blade, the locks are turned in opposite directions, and thus the blades prevented from being united; having selected your blade, and properly warmed and lubricated it, your next step must be to ascertain as correctly as possible the exact position of the patient's pelvis; the direction of the shoulders is of course no criterion, the great trochanter is the only guide to be depended upon, and is the more valuable because it also gives the direction, or nearly so, of the oblique diameters, this is important, because as the head is always more or less in one of the

oblique diameter; it follows that your forceps must be applied in the other. If it be the upper or right blade, which is to be applied first (and the head in the first position), you must guide it up to the head by the forefinger of whichever hand is most convenient, passing the instrument, as it were, beneath the great trochanter, and depressing the handle, so as almost to touch the patient's left thigh, its extremity must be slowly insinuated by a gentle vibratory motion between the head and passages, keeping your eye upon the situation of the trochanter and the general form of the pelvis as you gradually introduce it; if you attend to this point you will seldom fail to pass it up in the axis of the inferior aperture, and prevent it slipping into the hollow of the sacrum, which in the hands of a beginner it is so liable to do. As soon as the extremity of the blade has passed beyond the point of greatest pressure it generally needs little more than to be pushed gently upwards, as it will guide itself according to its degree of curvature; when it has passed to its full length the handle must be moved towards the perinæum, in order to afford sufficient room for the introduction of the second blade; this will be conducted in the same manner, except that instead of following the trochanter as your guide, the blade must be introduced in such a direction that the inner or flat surface of its handle shall be parallel, or correspond, to the similar surface of the handle of the first blade, this you should constantly bear in mind during the introduction of the second blade, for without attention to this point your blades will not be in apposition to each other, they will not therefore lock when brought together; in fact, the ease or difficulty of locking the blades depends entirely upon your attention to this circumstance. At the moment of locking you should be especially careful to surround this part of the instrument so entirely with your fingers as to prevent the soft parts, or hairs, from being pinched between them, nor is this always so easy to avoid as may be supposed, and requires great caution on the part of the operator, for it produces most acute pain, and frequently makes the patient give such an involuntary start as to run the risk of altering the position of the instrument.

When you have properly fixed the forceps, you must wait for the next pain, and as soon as it makes its appearance, its expulsive power should be assisted by grasping the handles firmly, and endeavouring to pull the head down in the direction of the inferior aperture of the pelvis. Recollect, gentlemen, that the forceps do not act only by simple pulling, they act very powerfully as a lever from side to side, and also by compressing the head. Wherever there appears to be considerable resistance, you will find it useful to tie a piece of tape pretty firmly round the ends of the handles, so as to keep up a constant pressure on the head of the child; this should be tightened at intervals as the head gradually

moulds itself to the passages. Your extractive efforts should be so varied in their direction, as to give the extremities of the handles a rotatory movement; these efforts should be made not only to imitate the duration of the pains as much as possible, giving the patient a little respite during the intervals, but also to allow the passages time to dilate as the head advances. When the head begins to approach the os externum, the handles should be gradually turned more forwards, and as it passes over the perinæum (which is to be supported in the usual manner) they must be directed completely forwards, or even somewhat forwards and upwards.

In applying the curved forceps you must be guided by the same rule in the selection of your first blade, as with the straight forceps, viz. that blade must be introduced first the lock of which looks forward. You will also remember that the pelvic curve of the instrument must correspond to the hollow of the sacrum. The direction, in which it is to be held at the moment of introduction, will vary somewhat from the former case, as the handles will have to be turned more forwards, moving gradually towards the perinæum as the blade ascends. The second blade must be guided by the handle of the first, as with the straight forceps, and the locking must be performed under the same precautions. In passing the curved forceps, you will find it frequently necessary to press the examining finger against the posterior edge of the blade as it is going up, thus preventing it slipping too far backwards towards the hollow of the sacrum. I need hardly say, that the extraction must be conducted in the same manner, and under the same precautions as in the former case, except that you must remember to turn the handles more and more forwards, as the head gradually descends. I have demonstrated the operation to you on the skeleton pelvis, because I think it is infinitely better than using the stuffed machine. You will find a plain pelvis, like the one before you, much more useful to practise on, than the best model which can be invented, because thus you make yourselves acquainted with the true direction in which the instrument should be introduced, and can detect all those little causes of impediment and difficulty which you are liable to meet with. I remember, when I was a student, teaching myself to apply the forceps in the following manner; having fixed a pelvis to my arm chair, I wrapped half a pound of tea in a silk handkerchief as smoothly as I could, and squeezed it pretty firmly into the pelvis; I now endeavoured to introduce the forceps in the proper direction as gently as possible, according to the rules which I have just given you; the blade required to be guided with some nicety between the pelvis and its contents, for if this was not attended to, it either stuck against the one, or dislodged the other; by this means I acquired that feel and management of the forceps which can only be obtained by frequent practice, and I can truly

say that it has assisted me more at the bedside than anything else.

By *turning*, gentlemen, is meant that operation in midwifery where the feet which had not presented at the time of labour, are artificially brought into the os uteri, and in this manner the child delivered. Hence turning comprehends two distinct acts; 1st, the changing the position of the child, and, 2ndly, the artificial delivery of it. This is no peculiar division of my own, for it was used by Stein, Aitken, Forster, Wigand, &c.; it is also adopted by Professor Naegele.

The first act, then, of turning, is that operation by which, without danger to the mother or her child, the position of the child is changed, either for the purpose of rendering the labour more favourable, or adapting the position of the child for delivering it artificially.

The indications for artificially changing the position of the child, with a view to facilitate the labour, or to render the position in which the child *cannot* be born more favourable, are all those deviations of the child's position from that which is necessary to a regular labour. You may ask me what is that position of the child which is necessary to a regular labour? I would answer, *where the long diameter of the child's body corresponds with the long diameter of the uterus*; as long as this is the case, it matters little which extremity of the child presents, for, as I have already shown you, as far as labour is concerned, the presentations of the inferior are just as favourable as those of the superior extremity. Any deviation of this, viz. where the axis of the child does not correspond with that of the uterus, brings it obliquely, or, in other words, we have a presentation of the arm or shoulder. The changing the position of the child, then, is indicated in all cases which require artificial delivery by means of the hand alone, but in which the child does not present with the feet.

The second act of turning consists in bringing, without danger to the mother or child, the child into the world with the feet first by means of the hand alone. This species of delivery evidently requires, as necessary premises conditions, a proper position of the child, viz., with the feet presenting, whether originally so or induced by art, and, secondly, a requisite size of the child, and a proper proportion between it and the pelvis*.

The operation of turning becomes very easily dangerous for the child, the more so the less favourable the circumstances are under which it is performed. In this respect it is far inferior to delivery by means of the forceps, for which reason, wherever it is possible, the forceps should be preferred to it. It is indicated in all those cases where nature is unable to expel the foetus, or which demand a hasty delivery of the child, but which cannot be attained by the application of the forceps.

The most common unnatural presentations

are those of the shoulder or hand and arm. They are frequently attributed to an oblique position of the uterus, but this is by no means correct, for the fundus may be directed to either side without at all influencing labour. The instant a pain comes on, it immediately moves so as to correspond with the line of the pelvic axis, and preserves this position as long as it lasts. When the child has been brought with its long axis into the axis of the pelvis, the faulty position ceases to exist, and now that it presents naturally the rest should be left entirely to nature. Deleurye pointed this out in 1770, and since that Boer and Wigand have done the same. It is a well known fact, that fewer children are born alive after turning, where the last stage of this operation has been accelerated, than where it has been left entirely to nature. The cause is this: the natural position of the foetus in utero is with the face bent forwards, the chin depressed upon the breast, and the arms crossed upon it. From what I have already told you, when speaking of nates' presentations, you will understand what results, if we attempt to hurry the labour by pulling at the feet. The chin instantly quits the breast, leaving a free space into which the arms slip, and as the child advances they gradually rise up above the head, so that the difficulty of labour is thus doubly increased, first, by having the long diameter presented to the superior aperture of the pelvis, and, secondly, by having an arm on each side of it. According to the experience of the celebrated Boer of Vienna, four-fifths of the children die after turning, when they have been brought into the world by pulling at the legs and body; while, if left to be expelled by the natural efforts, after the position of the child has been changed and the feet brought down, a full third of the children are saved.

It is a question of great practical importance, gentlemen, when is the fittest moment for undertaking the operation of turning. The most favourable moment is, *when the os uteri is fully dilated, and the membranes continue unruptured*. It is not always, however, that we can command such a favourable state of circumstances; the membranes may have been already ruptured, and yet the os uteri is not fully dilated: in this case we must not delay further, but proceed to dilate it gradually and gently, in order that the hand may be enabled to pass into the uterus. As long as the membranes remain unruptured, we may safely wait for the full dilatation of the os uteri. In the former case, where the liquor amnii has already escaped, we might wait until the uterus was so closely contracted upon the child, as would render turning extremely difficult or impossible; still, however, where the os uteri is hard, thin, and rigid, it will not dilate, and here we are compelled to wait until, spontaneously or by proper treatment, it becomes soft, cushiony, and extensible.

In all cases where the feet are towards the

* Naegele, MS. Lecture.

fundus uteri the patient should be placed upon her back, but where they are over the pubes I should be inclined to place her upon her knees and elbows; in fact, in every case where turning is very difficult, where the membranes have been some time ruptured and the uterus firmly contracted upon the child, I consider it by far the best position which the patient can take. Putting the woman upon her knees and elbows was recommended by Levret, especially where there is a pendulous belly, or the face turned towards the pubes. It was also recommended by Fielding Ould, as being the most convenient posture in cases where the child is to be turned. It has been objected against this position, on the score that women would never submit to it, but this is not the case. Under these circumstances, you will never find that the woman of good rank and education hesitates to comply with the wishes of her medical attendant. It is only in the lower classes of life that we see patients obstinately refuse to submit to this request, although they know it is to save their own life and that of their child. Where the circumstances under which turning is to be performed are highly favourable, viz. where the os uteri is fully dilated and the liq. amnii not yet escaped, there will be no necessity for the patient to alter her position, for we shall be able to turn the child with tolerable ease as she lies on her left side; but where the circumstances are not so favourable, I think that the mode pursued in Germany, viz. of placing her upon her back, is far preferable, and Dr. Dewees moreover recommends precisely the same plan; the patient should be placed across the bed, with her pelvis resting upon the edge of it, her back supported by pillows, and her feet resting on two chairs, at a proper distance apart and supported by assistants. According to the works on midwifery, we are told that we must introduce the right or the left hand, according as the feet are turned to one side or the other, but this is not so necessary as has been supposed, nor can we possess such a degree of dexterity and correctness of feel with the left hand as we do with the right, and in some cases of turning the position of the child cannot be ascertained before introducing our hand into the uterus for the purpose of bringing down the feet; for instance, in placenta prævia, where the placenta is attached to the os uteri, where a tremendous hæmorrhage has occurred, and where it is impossible to know how the child presents until the hand has entered the uterus, here we must always use the right, whether the feet be turned towards the one side or the other. Remember, gentlemen, that you cannot spare the strength of your hand too much, for if the turning prove at all difficult the strongest hand becomes exhausted; the hand, contracted, as far as possible, into the form of a cone, must be introduced into the vagina during a pain, as you are then ready to enter the uterus the moment the pain has ceased;

the other hand must be placed upon the abdomen to support the uterus, to assist in finding the feet, and in pushing the head into the fundus uteri; for the first purpose especially it is very important.

As soon, then, as the pain has ceased, you must introduce your hand through the os uteri; if, however, this be not sufficiently dilated, instead of merely pressing your hand up, you must gradually insinuate it through into the uterus with a twisting screw-like motion, so as to dilate the os uteri. If the membranes be not yet ruptured, it is directed in some works on midwifery to rupture them at once, before entering the uterus; but this method of practice is highly objectionable. It was a French author, Philip Peu, a man of great experience, who published his *Pratique des Accouchemens* in 1695, to whom we are indebted for the first correct rules on this important point. Peu recommended that the membranes should not be ruptured, but that the hand should be passed between them and the uterus until it came to the feet, and that then, and not till then, should the membranes be pierced. Deleurye strongly recommended this excellent practice in 1770, till which time it does not seem to have been at all noticed. Dr. Hamilton, in his "Elements of the Practice of Midwifery," paid attention also to this subject, and directs that in turning "the hand should be passed as far as the middle of the child's body, before attempting to search for the feet, or before attempting to rupture the membranes, should these remain entire till the aperture of the uterus will admit the hand."

The celebrated Boer has also highly praised this plan of proceeding. Hence after the hand has passed the os uteri it must be insinuated between the uterus and membranes until it comes as near the feet as possible; the membranes are now to be ruptured, and the feet taken hold of. The operation in this way is remarkably facilitated. From the membranes being ruptured at the side, the liquor amnii cannot flow off in any considerable quantity, and even this is prevented escaping by the presence of the arm in the vagina acting as a plug. In this manner the uterus is prevented contracting, and thus, gaining more power, the hand has plenty of room to act in it, and the child is moved with the greatest ease. Thus Dr. Hamilton says, "should the membranes be ruptured in the attempt, the operator must be ready to run up his hand as quickly as can be done with safety, when the waters being retained by his arm, the operation will be facilitated." This is of the greatest consequence in cases of placenta prævia. If a pain comes on whilst the hand is in the uterus, hold it quite still, for the slightest motion excites the uterus to longer and more powerful contractions; attempting to move it at this moment only tends to exhaust your strength, which ought to be carefully avoided; if it be kept bent

during a pain, an insupportable cramp is apt to come on, which deprives it of all power; it should be laid flat, with the inside towards the child. You must, however, never try to turn so long as the pains are violent, because the introduction of the hand is almost always a sufficient stimulus to induce pains even if they had previously nearly ceased. But I find the hour is expired, and must therefore delay the continuation of this subject till our next meeting.

Reviews.

The Edinburgh Medical and Surgical Journal.

We have selected from this admirable journal a few of the most interesting cases, of which we have given as condensed an abstract as the subjects treated upon would permit; and, doing this, we have carefully endeavoured to convey in our own language as clear an idea of the author's meaning as possible; but when it seemed impossible to deviate from his phraseology, we have not scrupled in taking it. The cases speak for themselves; they require no comment from us.

Cases of Anomalous Affections of the Respiratory Organs,

BY DR. GARDENER.

A peculiar convulsive action of the respiratory muscles.—This was the case of a young lady, æt. 17. "It may be described as a sudden spasmodic action of the respiratory muscles, producing a sound somewhat resembling a cough, but much louder and shriller, and differing from it in its general nature and character quite as much as in its intensity. Its sound may be said to be something between that of a cough and that of a howl." This was repeated every five or six seconds during her waking hours, but suspended during sleep, and commenced again in the morning. At this time the action was feeble and less audible, becoming louder and shriller, and in the space of an hour was quite audible all over the house, and even in the street. The voice was unaltered; it was impeded; but she possessed the power of suspending the action for a very short space of time, which enabled her sometimes to finish a sentence. It was supposed, from the time of life in which it commenced, that it might be connected with the functional changes incidental to that period. The catamenia, though scanty, were regular, but the disease continued to visit her occasionally long after their natural flow had been completely established.

The duration of the attacks was at first nearly a fortnight; afterwards they became less protracted. A considerable variety of treatment was employed, including a number of anti-spasmodics, tonics, and purgatives, and the local application of rubefacient plasters. Pur-

gatives were of more benefit than the others, of which class of remedies the tincture of black heliobore appeared most useful. There was always a very great discharge of solid fæces from the intestines, and the complaint ceased soon after. The Barbadoes aloes was subsequently given in small and repeated doses, together with steel and sulph. quina, which treatment was attended with advantage.

To the foregoing peculiar affection is appended—

A remarkable Case of Sneezing.

BY DR. BEILBY.

"A case important in itself, and which will give additional value to the one just related, from its obvious bearing upon the subject of it."

A young gentleman, thirteen years of age, had been affected with constant sneezing for three weeks; at first in rather violent paroxysms, with intervals of many minutes, but afterwards occurring from three to six times every minute, each sternutation occasioning now a comparatively slight degree of bodily agitation, and accompanied with a forcible expulsion of air between the nearly closed teeth, producing the sound "tchee." The nostrils were dry and red, the tongue was pretty clean and rather red, his general health was slightly disordered, and was said to be "very bilious." He had been taking considerable quantities of magnesia, on account of almost constant acidity of the stomach. Some months before he had suffered from headach and vertigo; he experienced benefit at that time from the application of leeches to the head. Cephalic snuff and two or three other nostrums were the only treatment usually adopted.

Blisters behind the ears, pretty free purging, and the injection of olive oil into the nostrils was the treatment adopted at first, and when, after a week, the sneezing was become much less frequent, perhaps about every two or three minutes, the carbonate of iron was recommended and the gradual exposure to cold air; at the end of five or six weeks he had no return of the sneezing, except when he was fatigued. The sneezing was always suspended during sleep, but recommenced immediately on waking, as he sometimes seemed to awake sneezing.

Case of Sudden Death from Perforation of the Pleura Pulmonalis, consequent on Disease of the Pulmonary Substance.

BY DR. GRAHAM.

John Meek, æt. 57, a labourer, was admitted into the clinical wards of the infirmary, on the 20th Nov. His symptoms were those of dyspepsia, and not particularly urgent. They consisted of weight and oppression at the epigastrium after meals, continuing till the contents of the stomach were vomited, often without, sometimes with, acidity, of pyrosis, and of frequent flatulent eructations; the bowels were rather costive; there was little thirst; the tongue was furred; there was emaciation, and

the legs were slightly œdematous. The pulse was quite natural; the abdomen was free from distension; the patient was without headach, gastrodynia, cardialgia, or other dyspeptic symptoms excepting those above stated. There was no tumour felt in the epigastrium, nor pain on pressure. His complaints were only of six weeks' standing, previous to which he asserted that his health had been good. His occupation had exposed him a good deal to cold, but not to hard labour, and his diet had been sufficiently nutrient. The treatment consisted at intervals in antacids, laxatives, opiates, bitters, blisters, and his diet was regulated, some steak being given to him daily, and the only vegetable matter allowed was bread. On the 4th December he complained much of hiccup, with flatulent distension, and on the 8th of pain under the right mamma, the pulse being 68 and natural. On account of this last symptom, a draught with nitrous æther and laudanum was given, and the pain immediately ceased. During his residence in the hospital the symptoms considerably abated. Before his admission the vomiting generally occurred twice daily—never after admission more than once, excepting when immediately excited by swallowing his medicines, and then very rarely, and for many days before his death he scarcely vomited at all; his spirits and appetite improved, and he thought himself recovering. After a good night he suddenly complained of great debility, and on the morning of the 15th asked for a cup of tea from the patient in the next bed, but before it reached his lips he died.

Sudden death very often occurs after long-continued organic disease of the stomach from rupture, and escape of the contents, but not with symptoms such as we had here, and the dissection was looked to with great interest, which took place twenty-nine hours after death. The following were the appearances observed.

Abdomen.—Omentum retracted, much thickened, and lodged in the left lumbar region; diaphragm pushed high into the left side of the chest; a considerable portion of the right side, near the ensiform cartilage, convex towards the abdomen. The stomach, lodged entirely in the left hypochondrium, contained a small quantity of coffee coloured turbid fluid; the peritoneal coat free from disease; great thickening towards the pyloric extremity: the diseased part was of several inches' diameter, having the pylorus towards one side; was elevated above the level of the mucous coat; its internal surface white, reticulated, over the greater part continuous, but supporting several rounded protuberances; its texture like soft and friable cartilage; its outline defined and circular.

Liver.—Right lobe adhered by a long narrow band to the diaphragm, its internal structure healthy. *Thorax* remarkably resonant on the right side, and there the intercostal spaces were raised to a level with the ribs,

though the subject was much emaciated, and the spaces therefore much depressed on the left side. The left lung was small, with numerous tubercles, particularly in the centre; the structure, in a comparatively small portion towards the edges, seemed tolerably healthy; and there was slight adhesion of the lower lobe to the pleura costalis.

The right lung was completely collapsed, pressed downwards and towards its root; the posterior part of the middle lobe contained some tubercles, the lower lobe adhered to the diaphragm by a copious deposit of firm lymph. Within this part existed a dark coloured cavity, about the size of an egg, having pulpy walls opening into the cavity of the pleura, and communicating distinctly with the bronchi. A small quantity of blood had lately been effused, and formed a thin clot, spread over and adhering to the pleura pulmonalis in the neighbourhood.

This case proves to us what indeed required no proof, innumerable cases having long ago established the fact, that very extensive organic disease may exist in organs of the utmost importance to life, without the patient being aware that any thing was wrong. This man never complained of a single thoracic symptom except the pain mentioned under the right mamma, eight days before his death. This was unaccompanied with the smallest fever, and immediately removed by an antispasmodic draught. Yet after death the appearances proved that the left lung had been long nearly destroyed, and the right considerably injured by chronic disease; and it is difficult to believe that the disease of the stomach could have been of such recent date as the patient had reported.

The chief interest in the case arises from the cause of death. It appeared that the patient had long breathed by the right lung alone, or nearly so. Subsequently the lung had become the seat of acute inflammation. The nature of the disorganisation Dr. G. thinks warrants him in believing that gangrene had occurred, although he could perceive no fœtor; but whatever had been the immediate cause of death, the pleura pulmonalis had been ruptured, air had escaped into the cavity of the chest, the lung, the only serviceable one, had been immediately compressed, and the patient suffocated.

Case of Tubercles in the Lungs in Extreme Old Age.

BY DR. CHRISTISON.

A man of the name of Watson, æt. 93, was admitted into the Infirmary with slight symptoms of general fever. Diarrhœa came on, and he sank rapidly after being in the hospital seven or eight days. There were no symptoms which attracted attention to the condition of the chest.

The body was examined chiefly with the intention of observing the natural appearances in so old a subject. There were some old ad-

hesions of the pleura. A great portion of the upper part of both lungs, but especially of the left, was condensed by grey hepatisation, amidst which, as well as in the less condensed portion of the lower lobes, there was seen a great number of small defined tubercles, most of them not bigger than a large pin's head. Near the apex of the left lung there was a small irregular cavity, without contents. There were some ulcers found in the lower part of the ilium.

It is worthy of remark, that the appearance of some of the organs of the body, whose changes are usually believed to indicate with tolerable accuracy the progress of life, was that of middle age only. The brain and heart were natural. The sutures of the head were strongly marked. The cartilages of the ribs free from ossification.

Case of Sudden and Unexpected Death, in which the Heart had only a single Coronary Artery, the Coats of which were Studded with Patches of Cartilaginous and Ossific Deposition.

BY DR. W. THOMPSON.

Mr. D., aged 49, was found dead in his bed with his eyes closed, his arms by his side, and every thing betokening his having died whilst asleep. Some years ago he suffered much from rheumatism, but had recovered, and was in the enjoyment of good health. He had had flying rheumatism in different parts of his body, at last settling in a leg or arm for ten days or a fortnight before his death, but complained of no other ailment. It was mentioned by one of his friends that he disliked walking fast.

Heart of natural bulk; depositions of bony matter at the roots of two of the aortic valves; a single coronary artery with bony and cartilaginous depositions, particularly hard at its mouth, and extending in small patches down its ramifications.

Case of Diseased Thymus Gland.

BY ALEX. HOOD, ESQ.

The patient in this case was about 15 months old, and of full habit of body. It was observed first about four or five months ago, that when she was surprised or irritated she was threatened with suffocation from some obstruction in respiration. In the course of the last three or four weeks she was seized with two or three fits, but in such a severe form, that respiration was for a brief period suspended. Her recovery from these attacks was rapid, and it seemed to have no unpleasant consequences, for her appearance in every respect indicated a high state of health. Soon after, while running on the floor, she fell, and suddenly expired in one of these fits. The child died in the fifth fit or attack.

Dissection.—There was no marked deviation from the natural and healthy appearance in the condition of the brain or its membranes.

On opening the thorax a small quantity of water was found effused in the pleura and pericardium. The thymus gland was examined with much care, and exhibited the following appearances. The thin and flat portion of the gland which usually expands downwards on the lungs, was removed by absorption. One portion of the gland rested over, and pressed upon the right subclavian vein; while another part of it lay over the subclavian coming from the left side, while a portion of it, in continuation of the part lying over the vein, extended upwards and backwards, and passed behind and under the vein, so that the left subclavian had three-fourths of its trunk completely embedded in the gland. When the gland had been carefully removed by dissection, the vein at this place was obviously contracted. The weight of the gland was not ascertained, but when put into a measure glass it displaced five drachms of water. The gland when cut into contained a considerable quantity of cream-coloured fluid or purulent matter. The mesenteric glands were in a scrofulous condition, and contained also cream-coloured fluid or purulent matter, though in small quantity.

Case of Obliteration of the Vena Cava Superior, at its entrance into the Heart.

BY DR. REID.

The above was found in a subject brought to Dr. Knox's dissecting room. The obliteration was two inches in extent, and formed, in the usual situation of the vein, a rounded cord of a cartilaginous feel, firmly connected to the surrounding parts, particularly to the anterior surface of the right bronchus, at the division of the trachea, by firm cellular tissue. Around it were several calcareous deposits, apparently connected with the bronchial glands. On the inner surface of the auricle, the entrance of the vein was only marked by a slight depression, and the auricle at this part formed a kind of digital pouch. The large veins at the root of the neck assisted in the usual way to form the vena cava superior, which became suddenly impervious at the part above mentioned. The vena azygos was twice its natural size, and became suddenly impervious where it joined the obliterated cava. The right intercostal veins were much enlarged, and a vein of the size of a common quill passed between the cava, immediately before its obliteration, and the upper part of the vena azygos. The vena azygos was joined at the usual place by the vena demiazygos, which was more than twice its natural size. The intercostal veins of the left side were also considerably enlarged. On blowing air down the azygos and demiazygos, they were observed to retain their large size as low as the diaphragm, and to form several plexuosities. The air passed freely along the enlarged intercostals and superior lumbar veins, and filling the vena cava ascendens. A vein of at least the size of a writing quill, formed by a branch from each of the azygos veins,

passed through the left side of the aortic opening, and joined the cava inferior.

All the systemic venous blood of the body, except that of the coronary vein, being poured into the right auricle by the vena cava inferior, that vein was also considerably enlarged, admitting the passage of three fingers.

The exact manner in which the blood passed from the large vessels at the lower part of the neck to the enlarged intercostals which entered the azygos veins could not be examined, as the heart had been destroyed by previous dissection.

Though the azygos, intercostal, and lumbar veins were all enlarged, yet it was difficult to conceive how the whole of the blood of the cava superior could pass with the necessary facility into the cava inferior, particularly as it was a retrograde motion.

The appearance of the parts around the impervious portion of the cava furnished no perfect clue to any supposed cause of its obliteration; it is, however, probable that the calcareous deposits around the vein were the remains of some enlarged bronchial glands, which, by their pressure upon the vein, produced its obliteration.

The subject was a female, about forty years of age, and died under the care of Dr. Smith, who furnished the following particulars of her case:—She was admitted into the charity workhouse, labouring under symptoms of hydrothorax. There was general anasarca, great difficulty of breathing, livid countenance, inability of lying down, scantiness of urine, pulse frequent, small, and irregular.

She was relieved of these symptoms by the use of diuretics. Shortly after her symptoms relapsed; the same remedies now produced no relief. She died rather suddenly under an aggravation of all the symptoms.

Inspection.—The right cavity of the thorax was full of serum, and the pleura costalis was much thickened. On the left side there were strong adhesions between the pleura pulmonalis and costalis, and the latter membrane was in many places fully three lines in thickness. The kidneys exhibited strong marks of Bright's disease. This woman had led a very irregular life.

Need we say that this journal should be read by every practitioner; by those who have an interest in their profession we doubt not but that it will.

FOREIGN MEDICAL LITERATURE.

Reflections on the Present State of Medicine in France.

BY DR. ST. GEORGE RANSOL,
Physician at Lucm.

BICHAT, extolled equally by the physiological, anatomical, and eclectic schools, is generally considered as the founder of our present physiology and pathology, and would doubt-

less have become an excellent physician, had not a fatal fall down stairs terminated his career at the early age of twenty-nine years. In the proem of his "Anatomie Generale," which strongly advocates the system of Brown, mixed with much real science and a great deal of absurdity, we find these remarkable words,— "What is the use of observations, if we are ignorant of the precise and absolute seat of the malady?—One might note the symptoms of affection of the heart, lungs, and gastric viscera by the patient's bedside from morning till night, for twenty years, to no purpose, as nothing but a tissue of contradictory errors could possibly result from it." And these unfounded expressions, taken literally, have been the source of all the pathological hypotheses of our time. But I would ask the partisans of M. Bichat, whether the descriptions, left us by Hippocrates, of the pathognomic symptoms of maladies, are not yet striking for their exactness and truth, and perfect models of clinical observation? Yet he was not a dissector, nor was Areteus of Cappadocia, whose works, by the bye, are not sufficiently read; has he not also transmitted to us faithful and most excellent descriptions of a multitude of acute and chronic affections?—and how closely do we follow even now his therapeutic treatment? Copious bleedings in visceral inflammation, and cupping, now too often replaced by leeches; in saburral affections, vomits and purgatives; in colics, baths and sedatives were the remedies he applied. And what more do we now know of the treatment of maladies of which that acute observer has given us a description?—Almost nothing; except indeed with reference to pharmacy, considerably improved and extended since his time; not, then, to our pathologic anatomy certainly, but to the perfecting of the natural sciences, and more frequently to chance, are we indebted for our therapeutic advancement.

Sydenham, one of the most skilful of his day in the healing art, whose works will live as long as the art itself, did not devote his great abilities to the examination of the dead. In his writings we find no descriptions of openings and examinations post mortem, that fruitful theme, which now gives birth to hundreds of volumes constantly issuing from the press at Paris, and which are good for nothing but to send those to sleep who have the patience to read them; the clinic of M. Andral, for example, in five volumes, the two first of which contain matter worth attention, the three last scarcely anything but post mortem examinations, and the essence of the whole might be compressed into one. But we do not understand the art of generalising in Paris, only that of detailing, which to the enlightened physician is insupportable. Nor can this mania for multiplying clinics tend in the slightest degree to the progress of the art. That which we really want, and are likely to want whilst the present mode of writing con-

tinues, is an able concentration of the dogmas of experience and observation of ancient and modern times.

With reference again to those inconsiderate and anti-clinic expressions of the young and lamented Bichat, it is to be observed, that maladies exist in the living not in the dead body, that the organic alterations found in the latter are often the effects of the primordial symptoms of the malady, or of humoral depravities, the just appreciation of which defies chemical acumen. Nevertheless the examination of the dead has its utility; we discover the seat of the malady, and sometimes the cause of symptoms previously inexplicable; it proves also how utterly powerless the efforts of art must be where there is disorganisation of the tissues; it may sometimes enlighten the practitioner as to the diagnosis and treatment of maladies; but it is no less certain, that from this branch of pathology we derive less assistance than from therapeutics. Without, then, depreciating the use of this mode of investigation, to which in truth I should incline with ardour were it possible, I have always deplored those fatal abuses of it which for sixteen years have resulted to the human species.

M. Broussais, who considers himself the propagator of the doctrines of Bichat, contrives to render that, which was already sufficiently confused and obscure in them, absolutely chaotic; some, too, of our most assured and satisfactory dogmas he treats as mere fantasies of the ancients. Thus, despite of all the enthusiastic respect which his writings manifest for the memory of his illustrious and departed master, he actually destroys his system of pathology in toto. According to the boastful and acrimonious language of M. Broussais, until he threw light upon the medical art nobody knew any thing about it, but now, by his definite and decided praise of gum-water and leeches, he has most happily fixed the treatment of all maladies. Truly, it is not without reason, that M. Broussais has been compared to the celebrated Dr. Sangrado; that most spirited and admirable portrait of Le Sage's may indeed stand very well for that of all the systematisers of all times and countries.

The unfortunate dissensions existing amongst our practitioners, and especially the discord between the schools of Paris and Montpellier, I have long deplored. All the world knows that Montpellier has for many centuries been the first school of medicine in France. Founded about the end of the tenth century, it reached its highest point of celebrity towards the middle of the last, thanks to the super-eminent talents of Sauvages, Barthez, &c., not forgetting Bordieu, who, though he never obtained a professorship, was justly celebrated, and may with strict propriety be termed the father of modern physiology. At that epoch most of the professors of the schools of Angers, Toulouse, Besançon, and even of Paris, either studied altogether, or perfected their studies at that celebrated University, then one sole doc-

trine of pathology existed throughout France; what has caused the destruction of this unity, and raised in its place an obstinate, bitter, and prolonged dissension? The causes, if I mistake not, are these:—the School of Paris, tired of its subservience and comparative inferiority, was waiting a favourable moment to assert its independence, when out burst the Revolution, overturning in its horrid career all political institutions, all scientific establishments, and abolishing every academy and university of medicine. The professors of Montpellier ceased not to remonstrate, and Paris, from its numerous and immense hospitals, became the centre of medical education; thither flocked all the youths destined for the profession, and, under the Desaults and Pelletans, &c., received their instruction. The government of 1793, finding it necessary to have a great many surgeons in the midst of a Continental war, created schools of *health*, as they were termed, and M. Baumes, already decked with long-acquired academic honours, filled the professor's chair.

Meantime M. Pinel, ever jealous of the fame of Montpellier, from which school he at length entirely separated himself, endeavoured to found a Parisian school; and further spurred, it may be, by the irresistible action of the Revolution, put forth a nosological treatise; a jargon of uncouth and barbarous words supplied the place of the fixed and appropriate terms of art, and this miserable performance, rousing the attention of the medical world, affixed to his name a degree of celebrity, or rather of notoriety, which endured through the space of nearly twenty years. From the date of his career the unhappy schism between the schools of Paris and Montpellier may be very easily traced, and its augmentation and continuance to the visionary hypothesis of the young Bichat and his followers. Nothing can be more certain than that the School of Paris, since its separation from that of Montpellier, has been running from error to error, and has experienced the fate of all schismatics; it is divided within itself into a multitude of rival sects, each the enemy of the other.

Matters, however, now begin to mend a little, thanks to the journals of Montpellier and to the writings of Rouzet, Miquel, Bonquet, and many other medical men of the highest merit. It is indeed time that there should be a perfect reconciliation between the two schools, and that we should be enabled to cast aside the odious phrases, *that* is the doctrine of *Montpellier*, *that of Paris*, and substitute the more creditable phrase to all parties of *that* is the doctrine of *France*.

Note on the Treatment of Congenital Luxations of the Thigh.

BY DR. PRAVAZ.

After going over the history of congenital luxations of the thigh, successfully illustrated by the labours of Paletta, Dupuytren, Humber, and Morlaix, and by the interesting commu-

nications of M. Breschet to the Academy, M. Pravaz relates the case of a little girl suffering under that affection, which was treated with complete success at the *Orthopedal Institution of Paris*.

Case.—In the course of April 1831 a child three years old, daughter of a practitioner in the law in the environs of Paris, was brought to M. Pravaz for a confirmed lameness, with commencing distortion of the spine. On examination there was every symptom of luxation of the right thigh; the ascensional movement of the extremity of that bone on the external surface of the ilium every time the body rested on it; the flatness of the corresponding buttock and the extreme curvature of the loins; the whole of the right member was rather less developed than the left; walking very difficult, and painful if prolonged. The luxation had preceded birth, and some of these signs had been remarked a few days after it, but no idea of injury sustained during birth could arise, as it was a head presentation. The lameness increasing from year to year, attempts had been made to remedy the inequality of the two members by repose and a slight extension, but soon desisted from, owing to the wasting of the flesh from the inaction of the muscular system.

The success announced by M. Humber, determined M. Pravaz to attempt the cure; and, first, to obtain the progressive elongation of the femoral muscles by continued extension, he caused a mould to be made of the child's pelvis, and enveloped it in two pieces of wood suitably lined in the hollows and separable at pleasure by the action of a moveable screw, so that the pelvis placed between them might be firmly encased, the under case large and thick, to enclose the projections of the hips, and fastened in front by buckles on each side of the apparatus completed the means of contra-extension. For the extension, an iron cylinder, firmly stuffed with wool, was destined to enclose the limb; at its lower extremity a cord was attached and fixed to a bent lever, moveable round an axis and pressed by a weight of which the power might be varied by making it act on an arm of more or less length. All this apparatus was adjusted on the moveable orthopedal bed, that the child might use the muscular action necessary in aid of nutrition and the support of strength.

Three months of extension produced such an elongation of the muscles, that the ailing limb might not only be drawn to the same length as the other, but even made to exceed it a little. The reduction was tried by the following means:—A rod of wood, eighteen lines long and four and a half broad, with a hole at one extremity to receive a pivot, was fixed to the plane on which the child rested, the exact height of the articulation of the thigh; at the other extremity was a cross-beam like a gibbet, serving as a fixed point to a pulley of six cords, the moveable part of which was attached to the extremity of the

apparatus enclosing the limb. On gently pulling the free cord, a rotatory motion of the lever around its point was caused, and thus was accomplished at the same time the progressive extension of the extremity of the limb beyond its enclosure and the retention of the head of the thigh in its natural cavity, whether luxated below or in front.

In the first experiment, M. Pravaz was aided by MM. Berard, jun., and J. Guérin; but the extension being made a little out of parallel with the axis of the body, gave pain to the child, and the operation was deferred till the following day. This time it was resolved to make the abduction as far as possible, so as to gradually bring into action the tractive force at the same time that the thigh, seized as a lever of the first order, rested on one of the hands of the operator serving as a fulcrum, while the other raised the action at its utmost extremity. This manœuvre was completely successful. M. Berard felt the head of the thigh slide over the surface of the ilium, enter, and remain in its cavity. The two limbs were now of the same length, nor was any alteration caused by rubbing the thigh up and down, but a slight sensibility was manifested in the hip. The child was then left to repose; and, to prevent the reissue of the head of the bone, a thick cushion was interposed between the hip and its case, and a bandage embracing the pelvis and upper part of the thighs was tightly laced round the body. The pain experienced in the articulation appeared to increase during twenty-four hours, it then gradually diminished.

In about a month experiment was made to try whether the child could walk. The thigh did not, as before, become displaced, but its articulation was found not yet so firm as the other. To hasten, then, the reparative operations of nature, a mechanism was adjusted to the orthopedal bed, by means of which the child could move the limb as if walking; and afterwards, in pursuance of M. Breschet's advice, with the help of certain mechanical apparatus, the circular movements were rendered practicable. These movements produced more pain than simple flexion.

A few weeks after, the child walked with a firmer tread; the lameness, considerably lessened, now appeared the consequence only of the relaxed state of the articular ligaments, and the limb altogether had recovered its flesh, and was very nearly as plump as the other. At the expiration of three months after the reduction the child was removed from the hospital, but the treatment continued, and the amendment progressed, still, however, with fatigue and a slight inclination to the right when walking, with transitory pain in the articulation, but her health continues excellent, and there is not the slightest indication of a relapse.

M. Pravaz's deductions from the foregoing case are these:—

1st. All original luxations of the thigh, whe-

ther from primitive want of development, or of mechanic power, or even from an affection of the cotyloidal cavity analogous to that which produces spontaneous luxation, are deformities curable by art.

2nd. Even when the cotyloidal cavity is entirely wanting, it would be advisable to attempt to luxate the femur below and then outwards and upwards, the lameness would be less marked and the deformity less considerable; this was proposed in the above case, and approved by MM. A. and P. Dubois, Marjorlin, Berard, jun., and Lalourcy; and M. Pravaz is of opinion that one of Humbert's cases already offers an example of luxation in front, happily substituted for that operation above and behind.

3rd. The processes of Humbert are too complicated; but whatsoever process may be used, time must always be allowed to obtain the progressive elongation of the muscles.

4th. For the reduction, a strong abduction, aided by methodical pressure on the trochanter, is preferable to simple extension.

5th. When the reduction is effected, it is necessary, in order to ensure the success of it, that the limb should be exercised in various movements, the body continuing still at rest.

Notice of a Fœtus putrefied in the Uterus.

BY DR. VASSAL.

The serious maladies which result from the putrefaction of the placenta retained in the uterus after miscarriage, and especially after regular accouchement, sufficiently foretel the symptoms of putrefaction of the fœtus itself; this latter case is fortunately rare, but for that very reason ought to be particularly noted, that some light may be thrown on the union of both cases for the direction of the conduct of practitioners.

Madame X—, twenty-five years of age, of sanguine temperament and sound constitution, and already the mother of several children, had always been safely delivered, and at each pregnancy her embonpoint had remarkably improved. In the beginning of November, 1833, she used a bottle of Seidlitz water as a purgative; on the 7th her courses came as usual, though more serous and less abundant. From this date she began to feel indescribably ill at ease, with shiverings, more or less frequent, often during the day; at night oppressive heat, and, after dinner a distension of the abdomen, which compelled her to lie down; her embonpoint began to diminish.

December and January, courses as usual, but serous and little in quantity.

February 6th. She had a slight fall on the seat; on the following day, epoch of the courses, a sero sanguineous flow lasted three days; health declined more and more, despite of the continuance of a voracious appetite.

On the 1st of March, immediately on her return from a ride on horseback, she suddenly rendered from the womb about a porringer of blood, and instantly fainted. At seven in the

evening I saw her, and found her condition thus:—Excessively thin; skin yellowish, dry, and hot; pulse 80; tongue pale, moist, and coated; the right hypochondrium swelled and sonorous; the uterus was placed above.

I suspected the existence of chronic inflammation; however, I announced that the womb contained something, either a fœtus, a mole, or hydatids; but the continuance of the courses precluded the idea of pregnancy in the minds of all present, neither did any change in the breasts announce it.—Repose, milk, emollient, drinks, cataplasms on the abdomen; during night increased fever with copious sweats.

March 2nd. Pulse 100; ardent thirst; face red.—Twelve leeches to the anus. At midnight the sweats returned; three in the morning bristling of the hair and gnashing of the teeth; icy coldness of the whole body; cadaverous countenance; pulse scarcely perceptible; fever returned; then profuse sweats.

3rd, 12 noon. High fever; urine limpid; the uterus seemed to swell in a greater degree; at four, an access of cold.

4th. Every four hours, injections of a decoction of belladonna into the vagina, with a glass of very hot sugared water, mixed with a spoonful of orange-flower water, to be taken every five minutes as soon as the algid state came on; it succeeded, the cold lasting but twenty minutes.

5th. Same symptoms; cold state returning at different hours; a flow from the womb, blackish, thick, and of insupportable fœtidity; from the touch, I found that the uterus occupied the cavity of the pelvis, though examination by touch offered nothing particular; no uterine pains whatsoever.

6th. Return of the algid state; relieved by three glasses of very hot sugared water; flow from the uterus continued, but less thick.

7th. Early in the morning, pulse 102, towards noon 80; the cephalalgia ceased; skin supple and less hot; the flow more serous and much less fœtid, and with it, in the course of the day, several membranous shreds; with a great quantity of encephaloideous and sanguineous matter. Ten at night; the right hypochondrium less tympanitic and sonorous; pulse 70, and perfectly calm. This state continued until one in the morning, when, without effort or uterine pain, a fleshy mass was discharged, followed by an excessive flow of blood and most excruciating contractions of the uterus.

I saw her at five in the morning; countenance pale and affrighted; eyes salient and haggard; pulse slow, small and concentrated; in fact, the vulva was enormously distended at its upper extremity by a black homogeneous mass, the size of an adult head. At the entrance of the vagina was a second mass, considerably less; and the vagina itself contained a placenta as large as at the eighth month of regular pregnancy: this placenta had undergone no alteration in its normal colour or

density, but had no umbilical cord; its extraction was accompanied by swoonings, and a deep saffron colour of the skin. Cold water sprinkled over the face dissipated these alarming symptoms.

Treatment.—Chicken broth, an infusion of tilia with syrup of orange-flower, an antispasmodic potion, injections into the vagina many times a-day of a decoction of quinquina. From the fourth day substantial aliment. On the 8th she sat up a few hours, but her weakness was extreme;—diffusible tonics, sulphur baths. Her courses appeared on the 7th of April, returned on the 7th of May, and continued regular.

The expelled fleshy mass was a foetus of three months apparently, though the series of symptoms indicated a pregnancy of four completed months. All the integuments and cellular tissues were entirely dissolved; the muscles of a red-brown, flimsy, and friable to the touch, adhered to the bones only by their tendinous extremities. The bones of the limbs were entirely bare; the face deprived of its soft parts; the anterior fontanelle wide open; the skull void of the cerebral substance. The coronal was flattened in a vertical direction; its upper part separated from the parietals, and, like the antero-superior angles of these, appeared greyish and dried up, as if they had been long exposed to the action of the air. The abdomen was open, and without the digestive tube.

M. Vassal inquires, what could be the cause of the death of the foetus, and at what epoch did it take place? The primitive symptoms induce him to think that the uterus, at the time of conception, must have been affected with a subacute metritis. It seems at first as if the death ought to be attributed to the fall on her seat; but in that case would there not have been partial disengagement of the placenta, loss of blood, lumbar pains, &c.? or was it from the presumed morbid state of the uterus? It appears, indeed, highly probable that it was so; the walls of the uterus, hypertrophied by disease, must have contracted its cavity, and thereby prevented the development of the foetus. Abortion must infallibly be the consequence; on this opinion M. Vassal rests; but it accounts not for the putrefaction. Some accoucheurs have presumed that rupture of the membranes resulted from the fall, and thus gave access to the air. But the flow, which preceded the abortion by two days, refutes such presumption; besides, air is not indispensable to putrefaction; nor do the laws of physiology account for such a decomposition within the mother, says M. Vassal; and further, he is inclined to explain the matter by an intense phlegmasia, which, invading the whole cutaneous system and umbilical cord, would have terminated in gangrene. And a very remarkable fact may be adduced in support of his opinion.

A woman, *æt.* 19, of strong constitution and sanguine temperament, became pregnant, for

the first time, in 1806. Her health underwent no change until the end of the fifth month, when she began to feel exceedingly uneasy and depressed; troubled with fantastic appetites, frequent shiverings, accompanied with general heat, intense headach, and flushing of the face. She was bled frequently in the arm. At the end of the ninth month the pains came on in due course; the coverings formed a voluminous pouch. On its breaking there came a thick, blackish liquid, and of such insupportable fetidity, that it was necessary to throw open every inlet to the air. The delivery was prompt and natural; a living infant at its full term was born, but wanting the right arm, and with a circular cicatrix covering the scapulo-humeral articulation. "Struck with this appearance," says M. Vassal, "which the woman attributed to meeting a beggar with only one arm, I examined carefully the clots of blood, and found the humerus, radius, and cubitus, which I sent to Professor Chassier."

Now, could not that which took place in this case have happened also in the former? The maladies were the same—the results the same, except that in the one case the affection was general, and in the other limited. In the first case, the rupture of the umbilical cord must have accelerated death and the putrefaction. The placenta remained sound, and receiving all the uterine blood, must have become engorged, which accounts for its large size.

M. Vassal then endeavours to explain the morbid symptoms of the first case. He does not admit the absorption of putrid miasma, as the double obstacle of the amnios renders it impossible through the uterine membranes. And further, from the special irritation, often fixed, of the internal surface of the amnios, caused by the presence of a dead foetus, there arise little vesicles, closely grouped, filled with saline crystals, and lying one over the other like the scales of fish. M. Guillemot has preserved in alcohol a conception of two months; all the inner surface of the amnios, and the integuments of the foetus, are covered over with these crystals,—another barrier to the supposition of the absorption of miasma.

When the placenta is putrefied the absorption is incontestable; the uterus and the putrid matter are then in contact, and malignant fever almost constantly results. "If," says M. Vassal, "our theory be confirmed by facts, it must follow, that the putrefaction of the foetus is less dangerous for the mother than that of the placenta."

MILK.

THE scientific world in France is now engaged in verifying some curious experiments upon milk, particularly as regards its preservation. The discovery is a remarkable one; and if it is founded on reality will make a great revolution in a part of our alimentary regimen,

and in a very considerable branch of our agricultural industry. It is nothing less than reducing milk to a solid state, so that an inhabitant of Paris may get his supply from Normandy or Auvergne and preserve it in the same manner as sugar. The discovery has been made by M. Gabriel Gaimand Caux.

Reports of Societies.

MEDICO-BOTANICAL SOCIETY.

March 10th, 1835.

JOHN HANCOCK, M.D., in the Chair.

A COMMUNICATION from Dr. Hamilton of Plymouth, on the seeds of the *Coo-ee-choon-jaal-ye*, was read. This Indian plant grows near Riobamba, not far from Chimborazo, and is reported, by Dr. Bancroft, to be of considerable value in the treatment of the Mal de San Lazaro, or, what is commonly termed the Cacabuy. It belongs to the class and order Pentandria, Monogynia,—natural order, Violaceæ.

Another communication from Dr. Hamilton, on the *Cevadilla*, was then read. It is said to be antheimintic, diuretic, anti-rheumatic, and antispasmodic.

A paper by Dr. Hancock, entitled "Notice of a Plant called *Coomi-paru* by the Natives of Guiana," followed. The *Coomi paru*, or purple bush, is used to intoxicate fish, so as to enable the fisher to catch them with the hand. It grows to about eight feet high; the stem is jointed and very frondose; it flowers at all seasons of the year, and is constantly covered with leaves of a purple colour; the flowers are small and white. The fluid circulating in the plant is lactescent, and nearly as consistent as cream: it is so abundant as to trickle down in a small stream when the bush is wounded. Four drachms of the dried and powdered leaves are digested with six of proof-spirit in the sun, and form a tincture, from five to ten drops of which are a dose, to be repeated every four or six hours, in internal inflammations. When given in the dose of twenty or thirty drops it causes borborygmi, followed by a rash, or rather diffused patches with a slight but sensible elevation of the skin, attended with itching and increased perspiration. It appears, therefore, to act by causing counter-irritation. Venesection must be premised.

There is reason to believe that there is not only an excitement of the surface, but also of the whole intestinal canal; it is, in fact, a sort of temporary irritative fever, which is induced by the *Coomi-paru*, which tends to arrest the inflammation, giving great relief to the sufferer.

A seed of this plant taken internally acts as a powerful hydragogue cathartic, bringing away immense quantities of water per anum, and is of considerable service in cases of dropsy.

WESTMINSTER MEDICAL SOCIETY.

Saturday, March 28th, 1835.

DR. ADDISON, in the Chair.

MR. QUAIN said, owing to the long silence that had prevailed, he was prompted to inquire of the members their experience in the destruction of granular growths affecting the external coats of the eye, and the remedies employed, for he must confess that he had found them exceedingly unmanageable, and often requiring, if accomplished, several months to restore the tunics to a healthy state.

Mr. Greenwood considered that it was of the greatest importance to ascertain, first, whether the granular affections existed in an acute or chronic form, but he believed that the latter condition generally prevailed; and, secondly, how far the system was concerned in producing these unnatural growths, for it would be highly prejudicial to attempt their removal until their producing causes were rectified, for he was satisfied that all diseases of the eyes were complicated with a derangement of the constitution. As an application, he was firmly convinced that the liquor plumbi subacetatis, in its undiluted form, was superior to any other.

Mr. Rice proposed and advocated Mr. Guthrie's stimulating plan, which consisted of the combined agency of Goulard's extract and the nitrate of silver.

Mr. Horne suggested the use of one part of calomel to ten parts of sugar, blown into the eye *through a quill*.

Mr. Quain considered that he had given a fair trial to most of the remedies in general use, but whether he employed local applications, or topical, such as bleeding, blistering, counter-irritation, he was far from being satisfied with the result. He believed that the disease arose from bad treatment of other diseases affecting the conjunctiva; and if he offered a theory it would be, that he considered them to arise from an enlargement of the blood-vessels producing the tubercles which constitute the mischief, causing the nebulous appearance of the cornea.

Mr. Greenwood was proceeding to make some practical conclusions on the subject, when the able president reminded him that the time had arrived for Mr. Strettor* to lay before

* [When Mr. Strettor, at the former meeting, was requested to bring forward variola, it arose, we believe, from his having hinted that he was able to prove that the vaccine ichor loses its protective influence after the age of puberty, instead of seven or fourteen years, but on this essential point he made no remarks. If we could arrive at a satisfactory conclusion, to what extent vaccination did protect the system, we should then be enabled to set at rest what the public at large have long

the Society his remarks on small pox, which were done, to use the words of a member, with "great modesty and propriety," but we suspect his surmises for the most part were derived from theoretical reasoning, his practical inferences having been drawn from the bills of mortality, from which source he had drawn up tables showing the decrease of deaths from small pox since the introduction of variolous inoculation, and its subsequent great diminution through the sanative and powerful influence of vaccination. Mr. Stretton then propose three questions for discussion, which we pass over in silence, as the speakers disregarded them almost *in toto*; the discussions that ensued tending to prove the power of vaccine virus over small pox, and to what extent the system is secured by its use, these we shall briefly relate.

Mr. Greenwood thought that the vaccine ichor became, 1st, almost inert if a rusty lancet was used, or certainly not affording protection against variola, the vaccine matter becoming, he would almost be inclined to infer, oxidised; 2ndly, by amalgamating the two matters we are not able to produce a mixed eruptive disease, either the one or the other takes the lead, and probably passes through the pustular, skipping the stage of maturation, into the stage of incrustation; 3rdly, high temperature and great moisture are found to nullify its action; and, 4thly, he regarded the best criterion that we are in possession of, to prove that the introduction of the vaccine has produced a constitutional, as well as a local, effect, is, that we should have a well distinct indurated elevation, giving the appearance of two margins to the pock, surrounded by a circumscribed inflammation. This he considered superior to the test recommended by Mr. Bryce, which was instituted to prove that if, during the regular progress of cow-pox, a second inoculation be performed, five days after the first, the affection produced by this repetition, will arrive at maturity, and fade away, at nearly the same time as the pock arising from the first vaccination.

Mr. Leese, whose experience on this subject, we believe, is equal to any practitioner's in this metropolis, fully concurred with the last speaker, and, in fact, acknowledged that he had anticipated some remarks that he had intended to have offered; however he would add that all those cases of variola occurring after vaccination, and that had come under his immediate observation, he found that the patients had had, invariably, only one incision made, and, although some differ on this point, he felt convinced that we ought to endeavour to create as much disturbance in the constitution as possible; but our means, unfortunately,

expected from the profession, in part in vain, and what has almost solely occupied the attention of those practitioners who have endeavoured to investigate the subject.—*REP.*]

afforded us the power of producing only a very slight degree of irritation, but by making two or three in each arm, we certainly increased it, and thus placed the patients much more securely than they otherwise possibly could be rendered.

Dr. Sayer added his testimony in favour of the perfect security that vaccination afforded the human race, for having been several years on the continent attached to the medical staff, many thousand soldiers (the number, unfortunately, not named) under a medical conscript from the French government, were compelled to undergo, wherever the least doubt existed, re-vaccination, previously prepared by warm-baths, aperients, diaphoretics, and a few days' rest in the hospital, and the same restrictions were enforced with all the recruits, and the result was, that not a single case of small-pox occurred for several years, and the only two that he saw, happened to two individuals, one aged 25, the other 26 years, but they did not come within the power of the conscript.

Dr. Sayer afterwards related an interesting case, proving the prophylactic virtues of the vaccine virus over variola, in a remarkable degree. A child, aged 7 months, was carried by its mother for vaccination to the Small Pox Hospital on the 13th of the month; on the 23rd of the same month, the mother became affected with variola in its severest form; for seventeen days the parent suckled her offspring, but it remained in a perfect state of immunity, although in spite of liability of suffering through infection, and of receiving into its system a secretion naturally loaded with the poison.

ACETUM OPII SEDATIVUM.

To the Editors of the London Medical and Surgical Journal.

GENTLEMEN,—I shall feel obliged by your giving me a corner in your widely circulated Journal for the accompanying letter from an old habitual opium consumer; I use the word consumer in preference to any other, as it gives a pretty good idea of the quantity that these poor deluded creatures are in the habit of swallowing. It is requisite that I should state, that the patient from whom I received the letter which I forward to you, selected from a host of others on the same subject, became a slave to its prejudicial influence at a very early period of his life. The cause of his taking it having been removed, he gradually, after immense fortitude, discontinued its use for some years. About two years since he was attacked with rheumatism in its severest form, which required more active treatment than any case I ever remember encountering. This had no sooner been overcome, than the right eye was seized with violent ophthalmia, of the two it was more obstinate to remove than the former disease.

The chronic rheumatism my patient complains of is one of the ill consequences arising from taking the drug, for the relief of which small doses of the same substance proves the best remedy, or the sufferers gradually sink, or the sufferers assume another form. However dreadful it may be to contemplate, it is our duty to communicate, but this I must defer for the present, having lately occupied the pages of your periodical rather largely, which prevents me entering more fully into this patient's history.

Having received thanks from many of my professional brethren for the formulary of the acetum opii sedativum, I shall shortly send you for publication my method pursued for chemically obtaining the pulvis antimonalis, by which means I am enabled to obtain an article that is always of an uniform strength and may be relied on, and not like the present antimonial preparations in use, so much so, that many of our physicians think it matters not whether they exhibit ten grains or seventy grains, the result being pretty much the same.

I am, Gentlemen,

Your obedient and obliged servant,

J. H. HORNE, Surgeon.

5, Gerrard-street, Soho-square.

March 26, 1835.

DEAR HORNE,—You request me to give you my opinion of your acetum opii sedativum. In consequence of broken rest, arising from a long attack of chronic rheumatism, I have again accustomed myself to the use of laudanum at bed-time, and am in the habit of taking from 50 to 70 drops at a time, I had no hesitation in taking 25 drops of your opium; but this I found too much, producing all the symptoms which affect me by an over dose of laudanum, namely, an extreme headach all night, disturbed sleep, and total loss of appetite at breakfast time; it was not until the afternoon that I recovered from the effects of it. However I have taken it several times since, but in quantities of not more than 15 drops, and this I find sufficient; I have no doubt but that it is full three times stronger than any laudanum I have before taken. I find, too, its effects last for a longer time.

J. W. Horne, Esq.

PLAGUE IN EGYPT.

THE plague is raging to a frightful extent in Alexandria, and in Egypt generally, and it does not appear government has taken sufficient sanitary measures to prevent the introduction of this dreadful malady into this country, at a time when the importation of cotton from Egypt affords so many opportunities. There were several vessels loading at Alexandria for England and Scotland at the time 80 or 90 persons were dying per day at that place of the plague.

THE

London Medical and Surgical Journal.

Saturday, April 4, 1835.

COUNTRY MIDWIFERY ; FATAL CATASTROPHE—CORONERS' INQUEST—MANSLAUGHTER—RESULT OF THE TRIAL.

OUR readers will recollect that, in a leading article of our last number, we deprecated, in opposition to a contemporary journal, the admission into office of half nurtured and ignorant practitioners in our rural districts. A case has now been submitted to us, illustrating the propriety of our caution, supporting our argument, and well calculated to open the eyes of the public as to the sort of professional men they should employ.

At the Borough Assizes, held in Leicester on the 21st ultimo, William Sutton, aged 50, was charged by an indictment upon two counts; first, with having caused the death of Ann Gilbert by the *improper* and *violent* use of his hands upon her person, in attempting to deliver her in childbirth; and, secondly, by the verdict of manslaughter, *brought in by the Coroner's Inquest held upon the body of the deceased.*

William Sutton pleaded *Not Guilty.*

It appears, from the evidence of the first witness, Sarah Inskip, a widow and midwife, that she knew the deceased Ann Gilbert, and was engaged to attend upon her, and that she went for that purpose on Sunday night, 14th December last. The deceased was then in labour, her pains, however, did not increase so much as they should have done, and at six o'clock in the evening she was put on the bed. *The hand of the child first made its appearance, and it was alive, as the witness felt the fingers to move.* There were two

other women besides the witness in the room. This witness, upon perceiving that unaided she could not bring the child forth, requested one of her companions to go for Sutton, as he was the nearest *practitioner*. The woman went and brought Sutton back with her without delay. The midwife told him her difficulty, and begged him to *try*. The man Sutton proceeded to make an examination, and announced that he could deliver the deceased, but that the labour would last *an hour* longer. He tried and tried *from about half-past eight to twelve o'clock*; during this time he appeared attentive and never left the room. *He gave her a powder in a little warm water, and then her pains became freer*. The patient frequently expressed her doubts of his ability,—but he still continued his attempts: never said whether the child was alive or dead; at length, however, between twelve and one o'clock, the witness became alarmed, and sent out for “better” assistance, and a Mr. Paget attended, who, after examining the parts, said, “he doubted the deceased had been *kept back too long*,” he, however, *forthwith delivered her*. The child was dead, and discoloured like a dead child. Mr. Paget treated the case as it ought to be treated, but the woman died next day. On cross-examination, this witness said she considered Sutton to have had, in one case, “*very good luck*,” he had beaten her in her business, and in one “*most difficult case had succeeded in bringing forth a breech presentation*.” She acknowledged that Mr. Paget had delivered the deceased *very quickly*, but that the hands of Sutton, during his attendance, were, for longer or shorter periods, continually under the bed clothes,—no one meddled with the patient after Sutton, except Mr. Paget.

Elizabeth Palmer, one of the women

in attendance, corroborated the above evidence, and added that she frequently asked Sutton “*if he could do*,” but received no answer. He seemed *to use force*, and the poor creature said, “she could not bear him.” This witness judged from appearances that Sutton used *much force*. He gave the deceased *two powders to take, one half an hour after the other, which seemed to do her harm, as her pains increased*. Mr. Paget came after Sutton had been five hours with the deceased. This witness received the child when born,—the arm was in a very shocking state, *it was bruised from the shoulder downwards, and there were marks of the prisoner's fingers upon it*.

Elizabeth Slack, the other woman in attendance, heard the deceased exclaim, that “*she could not be delivered under his hands*.” Sutton, upon this, told her to hold her tongue, “*as it would backen her pains*.” Upon these women suggesting the necessity of farther help, Sutton discouraged it. This witness was never out of the room, except when sent out for Mr. Paget.

Mr. Paget deposed, that he was sent for to attend deceased; he arrived at about two o'clock; Sutton was in the room. Found the deceased with labour pains upon her, *and the infant in a position in which it is impossible for a full grown child to be delivered: the arm of it was protruding externally, swollen, bruised, the skin excoriated, and the bone broken!* “*No natural means could have broken the bone in the then position of the arm, nor produced the excoriation*. A child in this state ought to be delivered by altering its position, the operation of turning should have been performed.” This witness suspected strongly “that an attempt had been made to bring the child into the world *by other than natural means*; he

drew this inference from the contusions on the shoulder and the chest, these parts were swollen and livid." This witness examined the body after death in the presence of another surgeon, Mr. Stallard. They found the injuries which, in their opinion, caused death; the *laceration was in the side of the passage* (vagina), a laceration sufficient to cause death in the witness's opinion.

The *ocular proof*, however, of violence here was not made out, the prisoner was therefore acquitted of manslaughter, and retired, no doubt, with the consolation of knowing that his *skill* would in future be pretty accurately appreciated in the district where he *practises*.

In looking over the evidence in this lamentable case, the most striking point is the testimony of Sarah Inskip, the midwife. She had attended many cases of labour, and, although one of those persons who scarcely ever send for the surgeon until irremediable mischief has occurred, her evidence proves that in this case it was the hand of a *living* child which was protruded; and, finding herself unable to accomplish the delivery, she had recourse in her difficulty to Sutton, whom she had known before "*very lucky*," but whom she acknowledged to be *not* the most eminent practitioner in the place. (We add, God forbid!)

Now in a case of "arm presentation," which this was, and the child being alive, what was the most advisable course to adopt? Ambrose Paré's words are "that in all cases where the upper extremities present, turning must be had recourse to, and the child be brought down by the feet; and that if the midwife cannot accomplish this, she must send for a medical man who can."

Ambrose Paré, however, when he gave this injunction, although he might have

had Sarah Inskip in one eye as a midwife, most assuredly *had not* Sutton as a surgeon in the other; for how does the latter act in the emergency?—Why instead of proceeding *instantly* to turn, or if the contractions of the uterus would not allow of immediately turning, taking measures to relax the pains and procure their cessation for a while, by bleeding or opiates, or both combined, he takes the opposite method, and unwitting that such a presentation, unless altered, could never be delivered, encourages the action of the uterus, and renders the case at last hopeless! "He gave her a powder (probably ergot of rye, as Mr. Paget conjectured from its effects), in a little warm water, and then her pains became *freer*." No doubt they did; and no doubt the *surgeon's* manipulation became freer too, and the poor woman was kept on the rack of agony and suspense, doubting the efficiency of her assistant (a cruel doubt for one in her situation), as well she might for four or five hours! And this culpable trifling with the safety of a fellow-creature was continued until Sarah Inskip, in spite of her confidence in "*his luck*," became alarmed, and sent out for what she should have sought in the first instance—"better assistance." That assistance, though too late to save the life of either mother or infant, came at last. Mr. Paget arrived, and after examining the patient's parts, expressed his doubts that she had been "kept back too long," but forthwith, going the right way to work, he effected her delivery. That the infant was born dead, and discoloured "like a dead child," we think no one who reads the evidence can wonder at, nor will they wonder that the unfortunate mother died on the next day. But their surprise may be well excited that the tragedy should have been allowed to go on to this extent

when *effective help* might have been so quickly obtained; that when, according to the evidence of Elizabeth Palmer, *much force appeared to be used*, powders which increased the fruitless pains given, and the poor victim, guided by the instinct of nature, expressed her conviction that she could not be delivered under Sutton's hands, his efforts should have been longer permitted. These are matters for wonder, disgust, and abhorrence.

Again, if, after what has been said, any doubt can remain in the mind of the veriest tyro in obstetrics, that Sutton both misunderstood and mistreated this case, the evidence of Elizabeth Slack and Mr. Paget must at once dissipate it. The former says that, in answer to the poor patient's remonstrances, Sutton told her to "*hold her tongue as it would backen her pains*," thus displaying his ignorance of the proper method of treating the case; he also disapproved of sending for farther assistance. Mr. Paget's evidence we will not repeat; but it amply proves the extent of ignorance and heedlessness of consequences which contended for predominance in the mismanagement of the "lucky person" whose conduct has given rise to these remarks. We had almost forgotten to say he was found "not guilty."

The post mortem examination by Mr. Paget and Mr. Stallard we conclude our readers will duly appreciate: it proves much. We trust also that they will unite with ourselves in hailing the prospect before us of a speedy termination, by legislative enactments, to the impunity with which the unlicensed and untaught have hitherto practised our profession.

REGULATION FOR THE APPOINTMENT
OF SURGEONS TO VESSELS CARRY-
ING OUT EMIGRANTS.

IN our number of the 14th ult. our readers may recollect we made some observations on the neglect of government in not affording sufficient protection to emigrants during their transmission to our colonies. We then enumerated many of the defects of the system now carried on, exposed its abuses, and recommended such alterations and amendments as appeared to us essential.

We are now happy to announce that, since the article alluded to appeared, a bill has been brought in by Mr. Baring on the subject, embodying many of our suggestions therein stated, and calculated to serve the cause we advocated most effectually. In this bill provision is made for the more ample accommodation of passengers sailing from any port in the United Kingdom, or its adjacent islands, to our settlements in North America. The number of passengers is specified according to the burthen of the vessel, and the height between decks named, but not finally settled, that being left to be determined in Committee.

We may here observe, that the height named—five feet and a half—is too low; it should be *at least* six feet, and this could be as easily managed as the lesser figure. The height of the lower tier of berths from the floor of the deck ought also to be six, instead of three inches, as set down in the bill, for the purpose of affording room to clean underneath when necessary. The quantity of provisions, so far as relates to the indispensables of bread and water, is also *named* on a sufficiently liberal scale: about a gallon of the latter and one pound and a half of the former per diem to each passenger.

We could wish that the other provisions were also subjected to regulation.

We now come to that part of the bill which most interests our profession; it enacts that a physician, surgeon, or apothecary is to be carried, *rated on the ship's company*, whenever the number of passengers amounts to, or exceeds, one hundred, or, if under one hundred, sufficient medicines to be provided; this to be attested by two competent medical men. On this clause we must be permitted to remark, that allowing vessels to proceed to sea without a medical practitioner, when the number is less than one hundred, does not seem to be wise or justifiable. A master having 99 passengers would avoid taking the 100th, and thus defeat the object of the Act. This clause is not clear, also, as to whether the crew are included in the number; at all events it ought to be fixed at not more than 50. A former law, but not now enforced, limited the liability to ship a surgeon, for the vessel's purposes, to that number. We hope to see this altered when the Bill comes under Committee.

Another clause specifies, that two children, each under 13 and above 7 years old, or three children, each under 7 years of age, are to count as *one passenger*. This mode of rating, as regards room and provisioning, might be passable; but, as to *medical attendance*, it is bad; for we presume that the health of a child ought to be as fully provided for as that of an adult. A slight alteration in the clause, excepting its application in this point, would, we suggest, be desirable as well as reasonable.

There are many other clauses in the Bill, exceedingly well adapted to protect and ensure proper treatment to that hitherto scandalously neglected and ill-used portion of emigrants whose pecuni-

ary means are contracted; and we view with delight the safeguard thus proposed to be thrown around them. It is a proof that there is still some humanity left among the framers of our laws. One word more. This Bill does not extend to the regulation of vessels carrying passengers to Australia. Why is this? We know that abuses of the most desperate nature are perpetrated on board such vessels. The passage is thrice as long as that to our North American settlements, and a great portion of it is through a more oppressive climate. We know, also, that the grasping cupidity of the caterers for passengers to this part of the world is to the full as great as that of those engaged in the traffic proposed to be amended. We may recur to this point; but in the meantime rejoice in what has been gained, and sincerely hope to see the system, not long hence, reformed altogether.

DEATH OF DR. MATON.

WE regret to have to announce the sudden death of Dr. Maton, aged 61, which took place on Monday, soon after he had been paying a professional visit to the Duke of Sussex. Dr. Maton was a great favourite with the late Queen Charlotte and the other members of the Royal Family. He was an excellent scholar, and ranked high in the profession, as a physician and botanist. He translated Linnæus, and was a Fellow and Elect of the Royal College of Physicians. In private life he was an amiable, kind-hearted man, and paid upwards of seventeen thousand pounds for his late father, who had been Chamberlain to the Corporation of Salisbury. He was a constant patron of merit wherever he could discover its indications, and it was principally to his fostering

hand that Dr. Paris owes his being first brought into public notice. He was a bachelor, and amassed a considerable fortune. He held the office of Physician to the Westminster Hospital for many years.

NATIONAL VACCINE INSTITUTION.

It is with much pleasure we have perused the last report of this truly noble institution. It states that only 334 deaths from the small-pox have occurred in the metropolis within the last year; a number considerably less than have died in any year since the introduction of vaccination, and falling short, by at least 4000, of the average of deaths annually by small-pox, before the protecting influence of the cow-pox was discovered and promulgated by the immortal Jenner.

“Such a diminution of mortality by small-pox it is fair to attribute to the now almost universal adoption of vaccination, and we feel grateful to the provident liberality of Parliament for having maintained this Establishment in such authority and usefulness as enable it to answer every demand when and whencesoever presented to us, to supply the material for vaccination. Accordingly we have done so to forty-two applications from the Navy, to thirty-four from the Army, to fifty-three from Foreign Stations, and one hundred and seven from Dispensaries established in various towns of the country; and we think it right to mention, that all these Dispensaries acknowledge their belief, from experience, that nothing less than an Institution upon so large a scale as this national one can be depended upon to supply the authentic material for vaccination, at all times and on all occasions when it is wanted, with certainty and success.

“We have vaccinated of the poor last year 11,571, and have sent 83,191 charges of lymph.”

British Hospital Report.

WESTMINSTER HOSPITAL.

Cases of Erysipelas.

CASE I.—*Erysipelas Traumaticum*.—George Beazeley, *ætat.* 35, by occupation a bricklayer, was admitted June 11th, 1833, under Mr. Guthrie. In the commencement of May last, he received a severe contusion on the left leg from a brick, which was thrown at him, and to which injury he paid little attention, except applying poultices. He continued at his work until a few days prior to admission. About that time an attack of erysipelatous inflammation came on, com-

mencing, he says, in the groin, and running down the limb on the inside, as far as the contused part. He does not know any cause for the attack; had not been engaged in drinking previously, nor is he in the habit of intoxicating himself. He has had occasional rigors for the last two or three days; complains of severe pain across the brow, and burning pain in the limb affected; has not any appetite, but great thirst; tongue covered with a dirty brown fur; pulse small, quick, and frequent, 90; bowels open; stools *foetid*; cannot sleep; countenance anxious; wanders occasionally; the wound is in a very unhealthy state, approaching to sloughing; foot and leg swelled, with well marked erysipelas extending up the inside of the thigh, where the tumefaction is not so great.

The house-surgeon ordered aperient medicines and fomentations to the part. Was seen by Mr. Guthrie the same morning, who directed flour to be applied all over the parts affected with erysipelas, except the wound, which was to be poulticed.

R. Liq. ammon. acet. ℥ij.,
Carb. ammon. ℥iiss.,
Mist. camph. ℥vj.,
Tinct. opii. ℥ij.—Misce.

Fiat mistura, capiat coch. larg. ij., 8us horis.

12th. He passed a better night than he has done latterly; he wandered a little; however, he says he has less pain, both in the limb and also in the head; bowels have been freely opened; pulse is small, weak, and irregular, too rapid to be counted; considerable anxiety and depression of spirits; the erysipelas appears to be extending up the body, towards the arm, and across it to the other thigh; complains also of sore throat, for which he was ordered a gargle of ℥vij. inf. rosæ, and ℥j. potass. nitrat.

R. Ammon. subcarb. ℥iss.,
Tint. cinch. c. ℥j.,
Decoct. cinch. ℥vij.,

Fiat mist., capiat coch. larg. ij., tertiis horis.

Is ordered port wine, ℥vj. daily, and beef-tea ad libitum.

Half-past two, p. m. Pulse still very rapid and irregular, but it can be counted, 140; tongue cleaner, edges red.—Cont.

Half past seven, p. m. Pulse 132, irregular, but has more power; the sore on the leg is sloughing, but the man appears, on the whole, somewhat improved.—Capiat coch. larg. ij. mist. 2ndis horis.—Brandy ℥vj. daily.

13th. The erysipelas has invaded the pubes, scrotum, and upper part of the right thigh; vesications, containing a light straw-coloured fluid, on the left leg and thigh; eyes inflamed; dryness and inflammation of the fauces;

bowels open; stools still offensive; urine little in quantity, and high-coloured; features continue to wear an expression of great anxiety, and appear to be assuming the Hippocratic cast; he passed a very bad night; skin hot and dry: pulse small and weak, 140.—Cont. mist., adde ammon. subcarb. gr. iv. ad sing. dose.

14th. The night was better than the preceding one, although he slept but little; towards morning he began to wander, and tried to get out of bed; pulse small, and somewhat intermittent, 108; typhoid symptoms are becoming more and more evident; the phlyctenæ are larger, the fluid they contain darker; sphacelus is taking place around the wound, indeed the whole of the soft parts in the neighbourhood presents a boggy feel, and seem inclined to sphacelate; the patient is troubled with hiccough; there appears to be greater tumefaction of the limb; sordes about the teeth, hips, and tongue; the offensive character of the stools continues.—Cont. mist.

7 P. M. The sphacelus is spreading, and he is apparently sinking.

15th. Bad night, but appears to be a little improved this morning; water drawn off by the catheter last night; pulse less intermittent; slight moisture on the body; the patient is comatose. Mr. Guthrie and Mr. White saw him within half an hour of each other. Mr. G. ordered him to continue his medicine, and directed some musk to be added to the mixture, without expressing any opinion as to the termination of the case, which Mr. White considered would be favourable.

8 P. M. Is now rapidly sinking; the body and extremities are cold, and the pulse almost imperceptible; breathes with great difficulty, and continues moaning.

Died at 2 A. M. on the 16th.

Autopsy.—Erythematous blush over the greater part of the body; sphacelated spots on different parts of the leg and thigh; cellular tissue of the left leg sloughing, and infiltrated with a thick tenacious pus, which could be pressed out; coats of the left femoral vein thickened, but not otherwise diseased; the whole of the cellular tissue of that extremity loaded with bloody serum; the bone was not injured; the brain and its meninges were injected, and serum effused under the membranes; old adhesion between the pleuræ, and the left lung was gorged with fluid; abdominal viscera healthy.

CASE II.—*Erysipelas—Application of Leeches*.—Jane Hall, ætat. 23, was admitted into Anne's Ward, under Sir A. Carlisle, June 25, 1833. Three weeks previous to admission, she struck her foot against a stone, and broke the nail of the great toe, which excited some inflammation in the part, followed by suppuration. On the 23rd of this month, a blush of erysipelatous inflammation

showed itself, principally on the inside of the leg, running up the calf, and partially extending to the outside of the limb, also on the inside of the thigh about half way up, attended with considerable pain, heat, tumefaction, and tension of the extremity; pulse small and frequent, 96; tongue rather furred; bowels confined; no headach.

26th. Seen by Sir A. Carlisle, who ordered a poultice to the toe, twelve leeches, if possible, to be fixed on the very centre of the inflammation, which he directed to be covered with flour directly the leeches dropped off; a fracture cradle was placed over the limb, so as to keep the bed-clothes from it; he also ordered alkalies internally. This latter part was accomplished by giving a wineglassful of Sir A.'s mixture three times a-day.

27th. The erysipelas appears to be of a paler hue where the leeches were applied, and is certainly not extending; bowels well open; flour but scantily applied. Continue mist., et reapplic. farinam.

29th. Is much improved; the erysipelas has nearly disappeared, but just below the knee there is a circumscribed patch of inflammation, as if it were about to terminate in abscess; to be poulticed. An abscess formed, was opened, and healed; the latter part was rather protracted, in consequence of a second attack, a slight one, of erysipelas, owing to the application of strapping, which yielded to rest, purgation, and flour. She was dismissed August 13th.

CASE III.—*Erysipelas Traumaticum*.—*Leeches*.—Eliza Davis, ætat. 20, admitted Sept. 24, 1833, under Mr. White, for pustular inflammation of the cornea. Is subject to inflammatory attacks, chiefly affecting the lungs and the eyes. Various treatments were adopted. On the 4th October she complained of great pain in the eye, which was very vascular; in consequence, an incision was made in the left temple, but the blood came so slightly, that a cupping-glass was applied over it, and $\bar{3}$ xvj. of blood taken. The black ointment was then applied every other day, with the effect of removing the vascularity, and nearly clearing the cornea. While she was thus satisfactorily progressing, symptoms of inflammatory fever set in. On the 14th she complained of great pain in the head and limbs, with tightness of the chest; bowels not open; thirst and heat of skin; pulse full, throbbing, and frequent; had had two of Mr. Lynn's pills, which had not yet operated.—V.S. ad $\bar{3}$ x.

Hæst. Sir A. C. $\bar{3}$ iss.

Mist. salin. capiat coch. larg. ij. tertius horis.

15th. She feels almost constantly sick, and can keep scarcely any thing on the stomach; complains of great pain and tenderness of the scalp; inflammatory blush on the left temple, extending down the cheek; bowels freely

opened; pulse not so throbbing, but still full and frequent.—Ordered a poultice to the temple, and to have an effervescing draught three times a-day.

16th. Complains of pain in the head, body, and limbs; general soreness; erysipelas has attacked the left temple, cheek, and ear, also extending behind it; tumefaction of left eyelids, almost closing up the eye; is very feverish; tongue furred; pulse frequent; bowels very open by the medicine she had last night, being hyd. subm., pulv. antim. $\bar{a}\bar{a}$ gr. v.; ten ounces of blood were also taken by cupping from the nape of the neck; to have powder containing calomel and jalap, and continue the poultice; flour to the face.

17th. The erysipelas appears to be extending all over the face, which is very much swelled, partially covered with flour, the eyelids of the right eye are also tumefied; has constant pain in the head, for which, with the heat and tenderness of the scalp which existed, the head was shaved, and cold lotions applied; sickness continues; pulse small, but very rapid, 110; bowels not very open; constant thirst; says she cannot open her mouth so as to show the tongue.—Ordered pills of calomel and colocynth directly. Mr. Guthrie saw her to-day, and thought it a good case for the punctures, as recommended by Sir Richard Dobson.

18th. Has been occasionally delirious during the night, but is more sensible at present; did not sleep at all during the night; the punctures were not made, but two dozen leeches were applied to the temples yesterday evening; the erysipelas is not extending; pulse rather small, but quick and frequent; thirst and sickness continue; the leeches bled freely, and have not yet quite stopped.

19th. Passed a better night, but still wandered somewhat; was talking nearly the whole night; inflammation paler, and she is more sensible; bowels open; less heat of skin, and the frequency of the pulse is diminished; the eyes were examined, but were found to be unaffected by the disease.—Instillet. gutt. ol. oliv. Cont. Brandy, $\bar{3}$ iv., an ounce every three hours.

20th. The inflammation is much lessened on the face, and there is less tumefaction; the eyelids are less swollen, and she can separate them a little; she has less pain and tenderness of the integuments; the upper lip is very much swollen, and she complains of her mouth being sore; bowels not very open; slept but little during the night; continues sensible; the inflammation appears to be extending at the back of the neck, where it has a very defined termination.

21st. Had a better night; erysipelas rapidly disappearing from the face, but appears to be extending on the nucha, and also towards the throat; says the soreness of the mouth is lessened; the upper lip is less tumefied, and she can protrude the tongue better; it is covered

with a white fur; pulse quiet, of moderate strength, 90; no tenderness of the integuments of the face or the scalp, which is now transferred to the nucha, where she cannot bear the slightest pressure; bowels open.

22nd. Continues to improve; no tumefaction of the eyelids, and scarcely any of the face; bowels open; tongue still furred; pulse regular, but not full; good night; flour to the nape of the neck.

23rd. The inflammation at the back of the neck is evidently not extending, and she is altogether improving.

R. Acid. sulph. dil. $\bar{3}$ j.

Decoct. cinchon. f. $\bar{3}$ vj.

Tinct. cinchon. c. f. $\bar{3}$ j.

Capiat cyathum vinosum bis in die.

The four ounces of brandy to be continued daily.

From this date she gradually improved, but gained strength very slowly; the inflammatory affection of the eyes returned, and a seton was put in the neck.

CASE IV.—*Erysipelas—Use of the Ung. Hydrarg. Fort.*—John Kelly, \bar{a} etat. 11, a boy of a strumous habit of body, a patient of Mr. Guthrie's in John's Ward, had the right leg removed for white swelling of the knee-joint. The stump did not heal entirely, and he continued in the hospital for several months. A small unhealthy ulcer remained on the face of the stump which nothing could induce to heal. On the 4th of the September following, an attack of erysipelas took place on the face of the stump attended with considerable fever, flushed face, heat of skin, thirst, quick pulse; was ordered salines and aperients; to keep in bed and be placed on low diet.

5th. The medicine had acted well, but the febrile excitement appeared on the increase. To continue the medicines, and the stump to be enveloped in a poultice.

6th. The fever continues unabated; the inflammation is spreading up the thigh, and is covered with small vesications, containing a straw-coloured fluid; bowels open; tongue furred; pulse quick and hurried.—Cont.

7th. No improvement; was seen by Mr. Guthrie, who directed the application of the blue ointment, and, if that did not arrest it, a line of demarcation to be formed with the nitras argenti.

9th. The ung. hydrargyri has been freely applied, but has not arrested the progress of the complaint; the erysipelas appears to be spreading through the ointment, and receding from the surface of the stump, the vesicles which had been formed there drying up.—Rep. ung. hyd.

13th. The erysipelas has been gradually dying away, and the poultice is now to be omitted.

15th. The inflammation is again spreading.—Rep. ung.

18th. The erysipelas has disappeared; placed on full diet.

CASE V.—*Erysipelas Traumaticum*.—*Line of Demarcation by the Nit. Arg.*—John Stockley, ætat. 24, a journeyman butcher, residing in High-street, Marylebone, was admitted Sept. 15th, 1833, under Mr. Lynn. On Monday, the 9th inst., while engaged in taking down, in a hurry, a piece of meat from a hook in the front of his master's shop, he drove his right hand on one immediately below, which entered it on the back part, between the second and third metacarpal bones. He paid no attention to the wound, but continued to work until the 11th, when considerable inflammation, with tumefaction and great pain, came on, and shortly ran up the arm; the pain was so severe as to prevent his sleeping; he applied poultices, and had but little other treatment, until he entered the hospital on the 15th.

On admission, there was considerable erysipelatous inflammation of the hand, extending up the fore-arm, and a little above it; great tumefaction and increased heat of the part, attended with considerable pain and fever; thirst; pulse full and frequent, 96; pain in the back and limbs; tongue furred; bowels open; no headach. A circle, at least half an inch wide and apparently deep, was made around the arm by the nitras argenti applied about an inch and a half above the inflammation; thirty-six leeches were applied to the fore-arm, to be followed by fomentations, aperients with diaphoretics and small doses of tartarised antimony.—Low diet.

16th. Fluctuation is evident on the dorsum of the hand, on which an incision was made, but the integuments being much thickened it was necessary to repeat it ere the pus could be evacuated; about three ounces were discharged, which were not contained within the walls of an abscess, but diffused in the cellular tissue of the hand, and removed by pressure; the erysipelas is not extending beyond the line of demarcation; bowels open. Poultice to be applied over the whole hand, and continue the fomentations for the arm.

17th. Says he passed a bad night and was in more pain, but was relieved by the fomentations; the bowels have been open eight times in the course of the day; considerable discharge from the wound in the hand; inflammation on the fore-arm much paler; healthy inflammation forming around the eschar produced by the nitras argenti; the pulse is not so full, but is still frequent, 96; tongue covered with a yellowish fur. *Middle diet.*

18th. Was seen to-day by Mr. Lynn, sen., when the inflammation on the fore-arm had entirely disappeared, considerable discharge continuing. He considered that the case was not erysipelas.

19th. Poultice continued to the hand, and also one around the eschar. The fore-arm is quite recovered.

21st. The eschar produced by the nitrate peeled away to-day about three lines thick. Is doing well. Continue.

24th. Simple dressing applied to both places, which are healing.

27th. Nearly well.

28th. Discharged.

CASE VI.—*Erysipelas Phlegmonodes*.—Elizabeth Harper, ætat. 30, a washerwoman, and married, was admitted an out patient Nov. 28th, 1833, under Mr. Guthrie, with phlegmonoid erysipelas of the left arm. The disease did not occupy the whole of the arm, but only the outer part near the elbow, above and below it, and indeed all around it, with the exception of the inner part. The inflammation was severe, of a rose-red colour or rather darker, but not so deep as that of erythema, and the swelling very evident; the boundary of the swelling and redness well defined; the swelling pitted on pressure; and she said that the pain was so very great as to deprive her of sleep; is feverish; pulse quick and frequent; bowels open. Several incisions, three or four inches long, were made through the integuments into the cellular tissue, but not deeper. Some small arteries were divided, and bled rather freely; eight ounces were thus drawn; the redness of the arm was thus nearly removed, and the swelling very much diminished; the pain, before so acute, was scarcely perceptible.

The loss of blood made her feel faint. She was strongly advised to enter the hospital, but she would not agree to it.

R. Hydr. submur., pulv. antim., āā gr. v.
Pulv. jalapæ, gr. x.—Fiat pulv. statim.

R. Haust. efferv. ʒ iss. 2ndis horis postea sumend.

Simple dressing to the wounds, and cold lotion to the inflamed part.

30th. Did not attend yesterday. Suppuration is freely established, and she is in very little pain; the cellular tissue had rather an unhealthy appearance; pulse quiet and rather small; bowels open; slept well.—Ordered linseed-meal poultice, diaphoretic mixture, and cathartic pills. Owing to the irregularity of attendance, the notes of her case were not continued. She went on very well.

CASE VII.—*Erysipelas Phlegmonodes*.—Thomas Tooley, ætat. 50, a coal-heaver, of a sanguineous temperament, middle size, and rather stout; a great porter drinker; slipped down an area on the 16th of September, 1833, while carrying a sack of coals, and fell on the left hand and arm. He came immediately to the hospital, where the limb was examined, and found to be much bruised and lacerated, but not sufficiently so to warrant his admission as an in-patient; the bones were not broken. He was ordered aperient medicine, low diet,

to keep quiet, and to have the parts constantly wet with cold lotions. This plan was pursued for the next two days, but on the 19th his wife accompanied him to the hospital when he came to show himself, and reported that he had passed a very bad night, and was delirious. The whole hand and fore-arm were very much tumefied and inflamed; the integuments presented a doughy feel on pressure; the pain was constant and severe. A remarkable circumscribed tumour existed on the outside of the arm just below the elbow, elevated considerably above the integuments, and about the size of a penny-piece. Sensation of fluctuation very distinct on the outside of the arm; and he says he has had several rigors within the last thirty-six hours; indeed, shiverings are almost constant. The lacerated wounds on the hand and wrist are suppurating, but the discharge is unhealthy. Pulse quickened and frequent, 110; tongue clean; bowels open; skin hot and dry. An incision was made into the circumscribed tumour already mentioned, which bled very freely. He was immediately admitted an in-patient, and placed in Percy Ward, under the care of Sir Anthony Carlisle. He was ordered the diaphoretic mixture with aperient, and put upon low diet; the whole arm to be enveloped in a linseed-meal poultice.

20th. He passed a very bad night, unable to sleep. Two incisions were made by the house-surgeon, on his visit this morning, on the back of the hand, and one in the arm, through the fascia, giving issue to a considerable quantity of pus; the incisions bled freely; he was much relieved; is now sensible; pulse small, quick, and frequent, 100; bowels freely open by medicine.

21st. Passed a better night, but otherwise no improvement; discharge very considerable and rather fetid; pulse smaller.—Full diet.

R. Sulph. quinin. gr. x.; infus. roseæ c. fl. $\frac{3}{4}$ viij.—Capiat coch. ampl. ij. 3tiis horis. Anodyne at night.

22nd. Improving; pain lessened, and feels better.

24th. The pus appears to accumulate at the elbow, in consequence of its being placed lower than the hand: the elbow was accordingly raised by pillows, so that the hand became the depending part.—Pint of porter daily.

25th. An incision was made at the elbow, and the pus evacuated—discharge great. The pulse is stronger, and he looks better.—Adde sulph. quinin. gr. x. mist. To have half a pint more porter in the day.

26th. The discharge still appears to be burrowing in various directions: a considerable quantity can be evacuated by pressure. The two wounds in the hand were made into one by a cross-cut; the tumefaction is diminishing.

28th. Is much improved; discharge frec. Sir A. Carlisle thinks the poultice should be

discontinued, and the wounds dressed. The arm to be supported by strips of adhesive plaster, placed at the distance of an inch between each so as to allow a free vent for the matter. Pulse strong and regular.

Oct. 5th. Sir A. Carlisle has stopped all the stimuli and tonic medicines he was taking. Is restless and delirious, and there is a slight appearance of sordes about the teeth and lips; the discharge is greater, and he complains that the pain has increased very much.

Brandy, wine, and ammonia, were soon again had recourse to, but unavailingly; he continued to linger for some days, the symptoms becoming more and more typhoid, and the arm putting on the appearance of approaching sphacelation; the discharge sanguinolent and thin; the sordes increasing; great prostration; low muttering delirium; tongue dry, and covered with a brown fur; with a small and irregular pulse, marked the close of his life. On the 9th he was removed into Mark's Ward, but he was too far gone to derive any benefit from the freer circulation of air. Diarrhœa came on on the 16th, and he sunk the next day.

Autopsy.—Body very much emaciated. Head not examined. Chest—old adhesions of the right pleura; lungs loaded with mucus; heart healthy. Abdomen—Liver enlarged and granular, paler; gall-bladder distended with bile of an unusually pale colour: it contained ten gall-stones; other viscera apparently healthy. Left arm—Soft parts in a state of sphacelus; bones uninjured.

CASE VIII.—*Erysipelas Erraticum.*—Hen. Wren, æt. 25, was admitted, Nov. 19, 1834, into Northumberland Ward, under Mr. W. B. Lynn. Is a man of a bad habit of body and intemperate. About ten days previous to admission a woman threw a jug at him, by which he received contused wounds on the forehead and wrists. He attended this hospital as an out-patient, and the injuries were properly dressed. He says that he abstained from drinking after this. On the 17th he felt worse than usual, and he passed the succeeding night in pain, and was very restless, the scalp having become the seat of erysipelas. On admission, the inflammation was found to affect the right side of the forehead and the scalp, the eyelids of that side participating, evinced by their tumefaction, discoloration, and closure. The head was shaved, and fomentations applied. Adhibeatur haustus cathart.

The fomentations were omitted next day, and flour applied; the inflammation was extending; the pulse small, about 90; tongue slightly furred; bowels freely opened by the cathartic.

R. Carb. ammon. \mathcal{D} ij.

Dec. cinchon. $\frac{3}{4}$ iv.

Aq. cinnam. $\frac{3}{4}$ iv.—M.

Fiat mist., capiat. $\frac{3}{4}$ j. quartis horis.

21st. Was rather delirious during the night,

but is perfectly collected at present; the inflammation is disappearing on the right side of the head, but is invading the left, the left palpebræ being tumefied and closed; tongue more furred; bowels not open.—Hæbent pulv. aper.

22nd. Bowels well open by the medicine; scap more tumefied; tongue continues furred; pulse 100, very small; was delirious during the night.

23rd. Passed a better night; the tumefaction is diminished; the pulse is stronger, 96, and the tongue cleaner.

26th. The inflammation is now spreading down the face; the eyelids of each eye are much tumefied and inflamed, and appear as if vesicular. He complains of great soreness and pain, and cannot bear the slightest touch. He passed a restless and disturbed night; pulse 86, small and frequent; bowels open, stools yellow; tongue white; headach.—Ordered to continue the flour to the head, and to foment the face; to have small doses of the antim. tart. and cordials; olive oil to be dropped in between the eyelids.

29th. Inflammation lessened, and he is altogether improving; less headach; pulse stronger; tongue cleaner; lids less tumefied, and can be separated a little.

30th. Passed a good night, and is free from pain; is very much better; the inflammation is going off, and the pulse improving. The left upper eyelid has a small point of ulceration in its centre.

Dec. 2nd. Continues to improve; the swelling is everywhere decreasing, and he is gaining strength.

7th. The ulceration of the eyelid is nearly healed.

Was discharged, cured, a few days after.

CASE IX.—*Erysipelas Phlegmonodes*.—Robert Potter, ætat. 25, was admitted Feb. 5, 1835, into Burdett Ward, under Mr. Guthrie. He is a sailor (the third mate of a West Indian), a native of St. Kitt's in the West Indies. While coming to England in his vessel about the middle of January last, was wrecked off the Western Islands, and in endeavouring to escape in the boat, injured the right leg against the gunwale. He was exposed to all the rigour of the weather for two days and two nights; he was then picked up by the Eliza, an American brig, and brought into Liverpool within a week after. He shortly after determined on coming up to London, which he accomplished on foot. Hitherto he had experienced no inconvenience from the injury to the leg, but, during the journey to town, it became very painful. Notwithstanding he did not lay by directly on his arrival, but continued to walk about for a few days, when the pain and inflammation became so severe, he was obliged to give in; nothing else than a cooling lotion was made use of.

On admission he was found to be labouring under erysipelatous inflammation affecting the

anterior and outer part of the right leg, the part inflamed being tumefied, and of a yellowish red colour; the swelling well defined, tense, and pitting on pressure; touching causes an increase of pain. The general symptoms are insomnolency, headach, inappetency, furred tongue, shivering, &c.

An incision of about four inches' extent was immediately made through the inflamed part, which afforded him instant relief, and removed the tension; the cellular tissue beneath was sloughing. A poultice was immediately applied, a dose of house physic ordered, and he was placed on low diet.

He slept well the next night, and the symptoms of general disorder soon ceased; the slough soon after began to be detached, and by the morning of the 9th was entirely separated; the discharge was healthy, and not abundant. In a few days more, the poultice was omitted, the lips of the wound brought together by adhesive plaster, and a roller applied; he was also put on full diet. No bad symptoms interrupted the progress of the cure, and he was dismissed, well, on the 24th.

ROYAL COLLEGE OF SURGEONS.

NAMES of Gentlemen who received Diplomas during the month of March, 1835.—John V. Lewis, Mark-lane; James Harris, Farninbury; Thos. W. Dyson, Manchester; John Brown, North-place, Kingsland-road; James Lyons, Co. Limerick; W. F. Clerk, Glenmuckle, Aberdeenshire; W. Henry Bishop, Cheltenham; Robert Falkner, Bath; George Isdell, Winchester; George W. Hunter, E.I.; Booth Eddison, Nottingham; Shewbridge Connor, Ireland; Johnstone Vicars, Exeter; Joseph Douglas, North Audley-street; W. Hall, Hatfield; Richard O'Shaughnessy, Limerick; John Gill, Huntspill; James O'Loughlin, Ballinasloe; John Dickenson, Wrexham; Robert Eddowes, Loughborough; James Orwin, Wakefield; Hugh Tod, Edinburgh; Henry New, Hatton Garden; Walker Golland, Manchester; Owen Richards, Bala, Merionethshire; Hugh Goold, London; W. Barnard, Bramdean, Hants; W. H. Jenner, Ware, Herts; Thos. E. Eden, Threadneedle-street; David Lawrence, Pontypool; Charles V. Field, Rotherhithe; W. APOTHECARIES' HALL.

NAMES of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, the 26th March, 1835.—Samuel George Gregory, London; James Hindle, Norton; Edward Nolloth, —; James Parker, Tunbridge; Alexander Bridge, —.

MISCELLANY OF FACTS.

A Soft Water Company is now in full operation, but let them not become in their turn monopolists with freedom on their tongues; let them beware of that error. Their utility will ensure a handsome remuneration for their labour and outlay; whatever competition they may have to encounter, they should not show much less endeavour to crush.—It will not do.

Guy's pensioners under the Stationers' Company receive—some 1*l.*, others 15*s.*, or 10*s.* 6*d.* per quarter, but the total amount of pensions in the gift of this fraternity amounts to 300*l.* per annum.

Thames Water.—The number of common sewers which empty themselves into the Thames between Chelsea Bridge and the Tower is 88, exclusive of innumerable drains from streets, manufactories, and houses.

Sir David Barry has arrived in town from Ireland, where he was sent by the late government on a professional commission.

Medical and Physical Society of Calcutta.—The editors of a medical journal, recently started at Calcutta, soon after commencing their career, addressed a letter to the secretary of this society, containing suggestions with the view to establish a union between that journal and the society, which was read at one of the general meetings. A resolution was proposed and seconded, authorizing the secretary to enter into communication with the editors on the subject, but was met by a counter amendment, to the effect that the pub-

lications of the society should be continued as before, without reference to the *India Journal of Medical Sciences*, or any other publication. The amendment was carried.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

*At the Meath Hospital during the Session of
1834-5.*

LECTURE VI.

Case of Secondary Symptoms which made their Appearance soon after a Mercurial Course—Method of Treatment—Case of Syphilitic Eruption—Mouth suddenly affected by a small Quantity of Mercury—Effects of this on the progress of the Cure—Eruption preceded by Rigors coming on during the Course of Fever—Danger of Treatment—External Tenderness, Value of, as a Symptom in Inflammations of Brain, Lungs, Abdomen, &c., &c.—Vomiting considered as a Symptom in Fever—Its Treatment—Chronic Rheumatism—Successful Treatment of—Obstinate Case of Arthritis—Cure of, by Local Applications—Observations on the Effects of Mercury applied locally—Case of Syphilitic Iritis—Action of Belladonna in.

GENTLEMEN,—You have observed that we have two cases of syphilis under treatment, one in the female, the other in the male chronic ward. They possess no peculiar interest beyond the ordinary run of syphilitic affections, still they deserve a share of your attention; for it is on your experience of individual cases, much more than on the knowledge derived from books, that your treatment of this obscure and Protean malady will depend.

It is now more than a year since the female patient received the syphilitic poison into her constitution. What the nature of the primary sore was we cannot ascertain, but from the account she has given it seems to have been true chancre. Some time after this occurred she got sore throat, articular pains, and an eruption, for which she was treated in this hospital about ten months since, and dismissed apparently cured. The disease, however, returned in a few weeks, and she has been

labouring under its effects up to the present moment. Three circumstances in this case demand our attention; first, the reappearance of syphilis after a mercurial course, for she was mercurialised here soon after her first admission; secondly, she exhibits a degree of syphilitic cachexy, being rather pale and emaciated; and, thirdly, the slow progress which the disease has made in her system, being limited to a few blotches on the skin, some periostitic swelling of the bones of the leg, pains, and slight arthritis.

In treating this case, I intend to give mercury, so as to affect her system, and, having accomplished this, I shall keep her under its influence for some time. I shall also, should it appear necessary, order her a free allowance of the decoction of sarsaparilla. Under this treatment you will find that the eruption will soon disappear, the periostitic pains and swelling be removed, and the constitution begin to improve. She has been ordered three grains of blue pill and half a grain of calomel three times a-day, a quantity which you will generally find sufficient to bring on mercurial action in females. I have no doubt but that the disease will in this case yield to mercury in a very short time, and that her health will be completely restored. The failure of mercury in producing a permanent cure on a former occasion is no argument against its employment here; if there were no syphilitic taint in question, I do not know any remedy by which the cutaneous affection and the periostitis could be more effectually relieved. On another occasion I shall speak more at large upon this important subject, and shall bring forward facts in proof of the assertion that mercury may fail to eradicate the effects of the venereal poison at a certain period of the disease, and may nevertheless be capable of curing the disease effectually at a future time. This may appear paradoxical, but it is not the less true.

The other patient, John Kelly, presents an eruption of red scaly blotches extensively diffused over the trunk and extremities, and closely resembling psoriasis. This man, like many others, denies the occurrence of a recent, syphilitic taint, and gravely states that it is

some years since he exposed himself to infection. Instances of this kind are to be met with every day; patients will not tell the truth about these matters, and false statements tend to throw a darker shadow over a disease in itself sufficiently obscure. However, in this case the poison seems to have confined its effects to the cutaneous surface; there is no affection of the throat, periosteum, or joints. The eruption covers almost every portion of his body; it made its appearance two months before admission, and was preceded by feverish symptoms and pains in the larger articulations.

In undertaking the treatment of this case there is one practical point to be held in view. The man's general health is good, his strength undiminished, and his circulation active. I therefore ordered him to be bled, and have kept him for eight or nine days on antimonials and low diet. By preparing him in this way, I knew that the mercury which I intended to give him would act more rapidly on his system; and such was the case, for on the second day after he commenced using it his mouth became affected. But here a difficulty arose which in cases of this description is apt to embarrass our treatment,—the mercurial influence appeared much sooner than I expected or wished. He had been ordered three grains of blue pill and half a grain of calomel three times a-day, and on the second day, before he had taken six pills, salivation commenced. Now in all cases where mercury affects the mouth sooner than you desire, and as it were in spite of you, it will not do as much good as where its action proceeds regularly and in accordance with your purpose. It is a general rule that most benefit is to be expected from mercury where its action is regularly progressive, or where the quantity taken is in proportion to the effect produced on the system. Hence we look upon it as an unfavourable occurrence when a small quantity of mercury occasions sudden and copious salivation; such an event deranges our calculations, and tends to embarrass our practice. Now in this case the patient, after taking five pills, became salivated on the second day. We found we had been going on too fast; it was necessary therefore to pause, but not desist. We accordingly reduced the quantity of mercury to three grains of blue pill and half a grain of calomel, to be taken every second night. By these means we kept up a slight discharge of saliva, and the man's symptoms began to improve. The eruption is now disappearing rapidly, and it is to this point I wish to call your attention. What are the marks which indicate the subsidence of an eruption of this kind, and by what criterion are you enabled to judge of the progress of the cure? When the parts are about to return to their healthy condition three circumstances occur; first, the vivid red or copper colour of the eruption begins to fade; secondly, the heat of the affected parts becomes reduced; thirdly, the

excessive secretion of morbid cuticle is arrested, and the quantity of minute scales covering the blotches diminished. In such cases the affected parts of the skin are highly vascular, and the secretion of cuticle is morbidly excessive in quantity; hence the continued desquamation from the surface of the blotches. You should, therefore, attend not merely to the colour of the eruption, but also to the quantity of minute scales on each blotch, when you wish to ascertain whether an eruption is fading or not. You can judge of this by your eye, or you can tell it by passing your finger over the diseased surfaces. The fading of the colour of the eruption, the decrease of the elevation and roughness in the blotches, and the gradual disappearance of the minute scales, these are the circumstances by which you can ascertain the subsidence of a syphilitic eruption. As the cure progresses, you find the parts assuming a more natural appearance, the same quantity of morbid cuticle is no longer thrown out by the affected spots of corium, the blotches become smooth and lose their elevation, and, finally, the red colour of the skin disappears. Of all the symptoms, discolouration of skin is the last to recede, and it generally happens that enough has been done in the way of treatment, long before the skin resumes its natural complexion. If you were to continue the administration of mercury until the natural colour returned, you would very often push it to a useless and even dangerous extent. In such cases a faded brownish or dirty tinge remains long after the re-establishment of healthy action.

There is a case in the female fever ward which requires a passing observation. A young woman, previously in the enjoyment of good health, was seized with symptoms of fever after exposure to cold; she got rigors followed by headach, hot skin, thirst, nausea, and acceleration of pulse. It is unnecessary for me to detail the symptoms which attended her illness during the past week; I shall content myself with pointing out the symptoms which particularly attracted my attention to her case on Saturday morning. At that time her fever had increased, she complained of severe headach and restlessness, had foul tongue, thirst, and symptoms of gastro-intestinal irritation. Such matters, however, demand no very particular consideration; what chiefly fixed my attention was the occurrence of slight and transient rigors during my examination; I observed her shuddering three or four times in the space of a few minutes. On questioning her respecting these brief rigors, she informed me that they had occurred with more or less frequency for the last three days. Now, gentlemen, whenever you meet with a symptom of this description in fever, be on your guard; watch the case with anxious, unremitting attention, and never omit making a careful examination. It is in this way that one of the worst complications of fever, treacherous and fatal disease of the brain, very often commences. On ex-

mining this girl, we found that she had not only headach, but also acute pain referred to the left ear, the external meatus of which was observed to be hot and tender to the touch. In addition to this, we were informed by the nurse, that she had been seized with a sudden fit of vomiting shortly after we left the ward on the day before. Here was an array of threatening symptoms calculated to awaken attention in any, even the most heedless observer. A patient after exposure to cold is attacked with symptoms of fever, she has headach and restlessness, she then begins to complain of acute pain in the ear, darting inwardly towards the brain, and, finally, is seized with sudden vomiting. Under these circumstances, it is not difficult to form a diagnosis, and there can be little doubt but that the phenomena here present were indicative of incipient inflammation of the membranes of the brain. It is not easy to say whether in such cases the inflammatory affection of the membranes precedes the external otitis, or whether the inflammation commences in the external ear and spreads inwards, though I am inclined to adopt the latter supposition, and the circumstance of the fever and earach arising from cold seems to give an additional degree of probability to this view of the question. Be this as it may, there could be no doubt but that this girl was on Saturday labouring under incipient inflammation of the membranes of the brain, as denoted by headach, rigors, acute pain in the ear, and vomiting.

Here let me observe, gentlemen, that, in cases of this description, I look on the occurrence of external tenderness, not merely as an indication of internal disease, but also as a favourable symptom. I have remarked that in all cases where this happens, the physician becomes more speedily and seasonably aware of the existence of internal disease, and the remedial means employed act with a more decidedly beneficial effect. I would prefer having to deal with an inflammatory affection of the brain or bowels, accompanied by external tenderness, and would feel much more certain as to the result, than if this symptom were but faintly marked, or totally absent. This observation is founded on experience.

In treating this case, you have seen that I ordered relays of leeches to be applied in the vicinity of the affected ear until the earach ceased. I have long followed this practice of applying a number of leeches in succession for the relief of local inflammation, and I can state with confidence that the result has been, in the majority of cases, highly satisfactory. Some prefer the application of a great many leeches at once, but my experience speaks strongly in favour of the practice of applying a small number, repeated at short intervals, until the violence of the local inflammation is subdued. Relays of six or eight leeches will suffice in the majority of cases of pectoral, cerebral, or abdominal inflammation. In some, however, when the attack is violent, fifteen or twenty

must be applied at once; each succeeding relay may consist of a smaller number than that which preceded it. In this manner I have maintained a constant oozing of blood from the integuments over an inflamed organ for twenty-four, or even thirty-six hours. In addition to this, I determined to bring her system rapidly under the influence of mercury, and, with this intent, administered calomel to the amount of a scruple in the twenty-four hours. These means have acted favourably, and she feels much better to-day. (This patient perfectly recovered.)

Allow me to make one observation more which this case suggests. This young woman, you recollect, had, on her admission, some epigastric tenderness, which we removed by leeching, and she remained free from any symptoms of gastric irritation until last Saturday, when she got a sudden attack of vomiting. Now, *in all feverish complaints, where, during the course of the disease, the stomach becomes irritable without any obvious cause, and where vomiting occurs without any epigastric tenderness*, you may suspect congestion or incipient inflammation of the brain or its membranes. If called to a case of scarlatina, where there is severe vomiting, and perhaps diarrhoea, unaccompanied by thirst or epigastric tenderness, what should your practice be? Are you to direct your attention to the alimentary canal, and endeavour to arrest these symptoms?—No. The vomiting here depends on active congestion of the head, and such cases are very apt to end in coma, convulsions, or death, from disease of the brain. You are all aware, that in cases of injuries of the head, followed by congestion of the brain, vomiting is one of the most prominent symptoms. The same thing occurs in febrile affections attended with determination to the head. You are not to conclude that a fever is gastric because it commences with nausea and vomiting; this is a serious, and very often a fatal, mistake; yet I am sorry to say it has been committed by many practitioners, and I have been guilty of it myself. In such cases you should not waste time in attempting to relieve gastric irritation by cold drinks, and leeches to the epigastrium, or to check diarrhoea by chalk mixture and opiates; you should direct your attention at once to the seat and origin of the mischief, and employ prompt and effectual means to relieve the cerebral congestion. Where the disease sets in with severe vomiting, unaccompanied by distinct evidences of gastric inflammation, whether it be common fever, or scarlatina, or measles, or small-pox, I commence the treatment by applying leeches to the head, convinced that in this way I shall be most likely to prevent an approaching dangerous congestion of the brain. I am anxious to impress this observation on your minds, because I am fully sensible of its importance, and feel certain that you will derive much advantage from bearing it in recollection during the course of your future practice.

The next affection to which I shall draw your attention is chronic rheumatism, of which we have a well-marked instance in the man who lies in the chronic ward immediately under the window. He complains of pain, weakness, and numbness of the lower extremities, for which he used the decoction of sarsaparilla and minute doses of corrosive sublimate for a fortnight, without any obvious improvement in his symptoms. His complaint is of considerable duration, it being now fifteen weeks since he was first attacked. This I need not tell you is a very unpromising feature in his case. When rheumatism has continued for three or four months it becomes a very intractable disease; indeed, there is scarcely any affection which tasks the ingenuity, and tries the patience, of a medical man more than chronic rheumatism. In this case, however, we have been so fortunate as to hit on a remedy suited to the complaint; the man has been rapidly improving within the last fortnight, and is now nearly well. You will recollect, that when I undertook the treatment of this case the patient was free from fever, his general health but little impaired, his pulse tranquil, his appetite good, no remarkable tenderness or redness of the joints—in fact, nothing to indicate the existence of acute local inflammation; consequently, it would have been useless to have recourse to leeches or bloodletting, or to administer antimonials, nitre, or colchicum. In such cases as this a different line of practice must be followed; you must have recourse to stimulant diaphoretics, remedies which will increase the secretion from the skin, at the same time that they exercise a stimulating action on the nervous and capillary systems. Accordingly we prescribed for this man the following electuary, of which he was to take a teaspoonful three times a-day:—Powdered bark ℥j, powdered guaiacum ℥j, cream of tartar ℥j, flower of sulphur ℥ss, powdered ginger ℥j, to be made into an electuary with the common syrup used in hospitals. The guaiacum not only acts on the nerves, tending to remove chronic pains, but also acts on the skin: you will find these and other properties possessed by it detailed at large in your works on *Materia Medica*. Whether given in the form of powder or tincture it often proves an extremely useful remedy in cases of chronic rheumatism, where no symptoms of active local inflammation or general fever exist; where either of these are present it is inadmissible. Ginger has also a stimulant effect, although its action is much more limited. It is a favourite domestic remedy, and is very frequently prescribed by our rival candidates for therapeutic celebrity—old ladies—in cases of chronic, or, as they term it, cold rheumatism; and I must confess that I have seen some benefit derived from their specific—ginger tea. With these we combined sulphur, which exerts a peculiar stimulant operation on the skin and alimentary canal. Sulphur is an extremely active remedy, and singularly pene-

trating in its nature, finding its way into many of the secretions, and most of the tissues of the body. You will find it in the urine in the form of sulphates, and it is exhaled from the skin and mucous membrane of the bowels in the form of sulphuretted hydrogen. Having said so much respecting sulphur, you will perhaps inquire why I prescribed the bark? It is not easy to give a satisfactory explanation of this; but we know from experience, that in cases of rheumatism, after fever and local inflammation are removed, bark and other tonics have been found extremely valuable. The cream of tartar is given with the view of tempering the other stimulant remedies, it being known to possess cooling and aperient properties. The whole form a combination which is similar in its composition to a well-known popular remedy for rheumatism—the Chelsea Pensioner.

Having thus explained the general tendency of these medicines, and mentioned that they are to be made up into an electuary, it only remains to speak of the effect produced, and the dose or quantity to be given. I have stated that the ordinary dose is a teaspoonful three times a-day; this, however, will be too much for some, and too little for others. The object in every case should be to keep up a mild but steady action on the bowels, and to procure a full alvine discharge at least once a day. If the dose mentioned already does not answer this purpose, it must be increased; if the bowels are too free, it must be diminished. You should never omit making regular inquiries after the state of the bowels while the patient is using this electuary, for if these matters are neglected, the patient will not obtain the full benefit to be derived from it. Besides opening the bowels, this electuary acts on the skin, and frequently causes a rapid disappearance of the disease. I need not say that in addition to this I ordered warm-baths; they coincide in effect with the electuary, acting on the skin, and tending to relieve the rheumatic pains.

There is another very remarkable case bearing some affinity to the preceding, on which it may be necessary to offer a few remarks; I allude to the patient with sweating arthritis, to whom I drew your attention this morning. This poor man, who is somewhat advanced in life, has been labouring for several months under inflammation of the joints of a rheumatic character, manifesting itself by pain, stiffness, swelling, and probably some slight effusion into the synovial membranes. These symptoms were accompanied by profuse and constant perspirations, with a tendency to diarrhoea, circumstances which caused a manifest deterioration of his health and strength; he became pale, cachectic, and emaciated. His case had been very tedious and intractable; he had been a long time in the hospital, and had used all the most appropriate remedies, but without any appreciable improvement; his joints remained stiff, painful, and

almost useless, he was greatly reduced in strength, and entirely confined to his bed. In addition to this his pulse continued unreduced in frequency, and this is always a bad sign; cases of rheumatic arthritis, attended by prolonged excitement of the circulation and copious sweating, are generally found to exhibit an intractable chronicity, and too often terminate in rendering the unfortunate patient a cripple for life.

Now in this case many remedies had been tried without effect, and the state of the man's constitution, combined with the circumstance of his having a tendency to bowel complaint, contributed to reduce still further the scanty list of our remedial agents. Alterative remedies to affect the general system were almost entirely out of the question, and a vast number of local applications had proved unsuccessful. It occurred to me here that some benefit might be derived from mercurial ointment gently rubbed over the affected parts, assisting its action by the use of rollers applied round the joints. Fortunately the experiment proved successful; in the course of a week or ten days the swelling diminished considerably, the pain is nearly gone, and the power of motion is returning. His mouth has become affected, but the relief experienced appears to be proportioned, not to the influence of mercury on the general system, but to its effect on each individual joint. As a proof of this, I may state that the man has been mercurialised before but without any favourable result.

Here, gentlemen, is an important point for consideration. A patient labours under a certain number of local inflammations, for which mercury is given internally so as to affect the mouth, but without any manifest improvement of symptoms; we afterwards try the same remedy in another form, we apply it locally, in the shape of ointment rubbed into the skin over the diseased parts, and we succeed in giving relief. This is a fact deserving of attention. You will perhaps ask me to explain this,—I cannot do it; but I can bring forward many other analogous examples. If you refer to Mr. McDowell's valuable paper on erysipelas, published in a late number of the *Dublin Medical and Chemical Journal*, you will find that many cases of this affection derived great benefit from the use of mercurial ointment, in fact, much more than they could by giving mercury internally. In the next place, I have met with many cases of enteritis and peritonitis where the disease continued after the system became affected by mercury, and I have observed that these cases yielded rapidly to blistering the abdomen and dressing the raw surfaces with mercurial ointment. Dr. Marsh and I attended a young gentleman lately, who had low fever, accompanied by a quick but feeble pulse, and great restlessness. About the tenth day, his belly became tender and exquisitely painful; he had thirst, diarrhoea, and other symptoms of enteric and peritoneal inflammation. Before

his illness he had been of rather delicate habit, and had further impaired his health by close study. He was therefore unfit for depletion, and of this we were convinced by the debility which followed the application of a few leeches. Under these circumstances we ordered a large blister to be applied to the abdomen, and the vesicated surface to be dressed with mercurial ointment. This proved eminently successful; the peritonitis, enteric irritation, and fever, soon disappeared, and the young gentleman recovered completely. The same thing is seen in many cases of pleuritis; the constitutional effect of mercury will fail in removing the affection of the pleura until it is applied locally. I might also refer to instances of common inflammation of the testicle, in which mercurial ointment smeared over the part has been found decidedly beneficial. It is unnecessary for me, however, to multiply examples, what I have stated give ample proof of the utility of mercury applied locally. When I was a student, it was the fashion to scout the doctrine that any distinct effect could be produced by the local application of mercury; our teachers laid it down as an axiom, that, to produce any sensible effect, it was necessary that it should first enter the system through the lymphatics. Thus, when you rub mercurial ointment over the liver to remove hepatic derangement, they said, before it could exert any influence on the liver, it had to pass along the thoracic duct, become mixed with the circulation, and manifest its peculiar action on the whole economy. Hence, in a case of hepatitis or testitis, it was deemed useless to apply mercurial ointment over the liver or testicle, since it had, as they expressed it, to go its rounds through the whole system, before it could affect either of these organs. This reasoning has an appearance of plausibility, but it is contradicted by facts. Numerous examples might be cited to prove that the greatest advantage may be derived from the local application of mercury, independent of any effect produced by it on the general system. How often do we see an incipient bubo dispersed by mercurial frictions, before any constitutional effect occurs? How frequently do we see laryngeal and hepatic inflammation relieved by the use of mercurial ointment without salivation? Do the beneficial effects, which we so often observe from the emplastrum ammoniaci cum hydrargyro, depend necessarily upon the mouth being affected? Is the relief which follows the use of mercurial ointment in erysipelas or testitis unattainable unless preceded by mercurial action in the whole system? Indeed, any person who reviews this subject dispassionately will see that the doctrine of a preliminary constitutional affection being absolutely necessary, in order to obtain the specific action of mercury on any particular organ, is wholly untenable; while, on the other hand, there is a host of evidence to prove that,

locally applied, it produces a primary and distinct effect, totally independent of its action on the general economy.

The last case to which I shall direct your attention is one of syphilitic iritis. A young man has been admitted this morning, presenting symptoms of secondary syphilis in a well marked form, but simple and uncomplicated by any previous treatment. He took no medicine for the primary or secondary symptoms, except two pills, which he got at a dispensary about two months ago, and which were not followed by any sensible effect. The secondary symptoms came on with pains and feverishness, and are at present extensively diffused over his body in the form of elevated blotches, of a character intermediate between the papular and squamous. About four or five days back he was advised to take a warm bath for his pains, but having to walk a considerable distance afterwards, the day also happening to be chilly and sharp, he got cold in returning home, and soon after experienced pain in the left eye, with lachrymation, and diminution of the power of vision. Had he been exposed in the same way while in health, he would probably get slight conjunctivitis, or sore throat, or bronchitis; but the case was altogether different with a man labouring under a constitutional affection, having a tendency to manifest itself in almost every tissue of the body, and prepared to modify every form of inflammation to which accident might give rise. Again, if the man's constitution was in a sound state, his feverish cold, or conjunctivitis, or sore-throat, could be removed by very simple means, such as bathing the feet, taking a little warm whey on going to bed, and some opening medicine the next morning. But here the state of the constitution occasions the substitution of syphilitic iritis for simple conjunctival inflammation, and demands a peculiar plan of treatment. You are all aware that persons who have taken mercury for syphilis, without being entirely cured, are very liable to get iritis on slight exposures. Some persons attribute this entirely to the mercury, but mercury in such cases merely acts by rendering the patient more liable to cold, so that when iritis occurs in a patient who has been under a mercurial course, it is not in consequence of the direct operation of mercury, but by its increasing his liability to be affected by impressions from cold. For the same reason the circumstance of his having taken mercury before is not, as some persons maintain, any argument against his using it a second time.

On examining this man, we found that he had some pain referred to the eyebrow, the eye also is more vascular than natural, and presents that appearance which is so characteristic of iritis; there is some alteration in the colour of the iris along its free margin, but no irregularity of pupil. Along with these symptoms, there is dimness of vision, and objects appear as if seen through a veil.

This arises not from any opacity of the cornea, or opalescence of the aqueous or vitreous humours, but from inflammation affecting the iris, ciliary zone, and, probably, the coats of the retina. In such cases, where the inflammation spreads from the iris to the ciliary zone, it would appear that the ciliary nerves and retina partake in the mischief, for vision becomes affected before we can discover any appearance of derangement in the optical instrument. The peculiar appearance of the eye in this man, the change of colour in the free margin of the iris, and the diminution of the power of vision co-existing with an eruption of the skin, point out the nature of the disease, and shew that the affection of the eye, though proceeding from a common cold, has been modified by the syphilitic taint in the constitution.

We next come to consider the plan of treatment to be pursued. In order to prepare his system for mercury, I have ordered him to be blooded, purged, and put on the use of antimonials for two or three days. Venesection, purging, and tartic emetic, may be of some use in relieving or arresting the symptoms of iritis, but I do not place any great reliance on them for removing the disease; I merely employ them as auxiliaries, depending on mercury for the cure. Here it may be necessary to observe, that there is considerable variety in cases of iritis. Some are extremely mild; there is no palpable sign of acute inflammation present, and the chief symptom is diminution of the power of vision. Such attacks are sometimes not perceived by the patient until some accident informs him that the sight of one eye is nearly gone. In other cases, after reaching a certain point, it begins to decline, and frequently terminates spontaneously. Others present symptoms of a more decided character, but still are free from danger. Every attack; however, where the inflammation is at all of an intense character, will go on to destroy vision, unless met by prompt and efficacious treatment. In this man's case the symptoms are not very acute, and hence there is no necessity for having recourse to mercury at once; the disease might certainly terminate in disorganisation of the eye, but it would be some weeks before this would be accomplished. On the other hand, there are cases which, if neglected, would destroy vision irremediably in the space of three or four days. Such cases require extremely prompt and energetic measures. But where iritis is not of a violent kind, you need not depart from the plan of treatment you would have laid down for the cure of syphilitic affections where no iritis existed. Here you bleed, purge, give antimonials and mercury, and you find that the syphilitic eruption and iritis disappear together. But where the symptoms of iritis are so severe as to threaten rapid disorganisation of the eye, you disregard the syphilitic affection, and direct your entire attention to the preservation of the eye. Here you bleed, leech, apply belladonna

to the eye, and give calomel in doses of ten grains or a scruple every third or fourth hour, so as to bring the system as rapidly as possible under the influence of mercury.

With respect to belladonna, I believe you are all aware of its value in iritis. Some think that its action is merely mechanical, that it dilates the pupil and no more; but I am firmly convinced that its influence is not limited to mere dilatation of the pupil. I believe that it acts on the vitality of the eye, and that when employed externally or internally it possesses the properties of diminishing the irritability of that organ, and thus tends indirectly to remove local inflammation. In scrofulous ophthalmia, where the eye is exquisitely sensible, where the slightest exposure to light causes intense pain and copious lachrymation, one of the best remedies I am acquainted with is belladonna given internally. Thus, you perceive that belladonna has not only a mechanical action, producing dilatation of the pupil, and tending to prevent adhesions, but also, by its influence on the retina and ciliary nerves, diminishes the irritability of the eye, and aids materially in effecting the removal of local inflammation.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXVI.

Turning—Cæsarean Operation and Section of the Symphysis Pubis.

GENTLEMEN,—You will recollect, that at my last lecture I endeavoured to impress upon your minds how important it is to preserve the membranes unruptured until the hand is altogether within the uterus, and the arm so completely occupying the vagina, as to prevent the liquor amnii escaping. To find the feet of the child we should pass our hand along the anterior surface of its body, as the feet are generally crossed upon the abdomen. If, however, we are not certain of the child's position, we must bear in mind the excellent rule of Dr. Denman, namely, that the hand "must be conducted into the uterus on that side of the pelvis where it can be done with most convenience, because that will lead most easily to the feet of the child;" but in arm presentations we can generally form a pretty tolerable guess how the child is situated, for unless the arm or body be unnaturally twisted, the palm of the presenting hand is always turned towards the inferior extremities or fore parts of the child. In pushing your hand upwards, never let the pressure be on the uterus, but upon the child, except, if possible,

upon its abdomen, for the uterus may be easily inflamed or even ruptured, while, if the child does bring a black spot with it, it is of little consequence, comparatively speaking; the parts of the child yield, whereas the uterus does not, and this fact is of considerable importance as to how you hold your hand at the moment a pain comes on. The child can scarcely receive injury from pressure of the hand, except upon the abdomen, and here it appears to cause death in a similar manner to what pressure upon the cord does, and should therefore be avoided.

If we feel the knees, they will easily conduct us to the feet, or they may be pulled down until the feet come within our reach; if we can only get hold of one foot we should bring it down; but it is better to bring down both if possible. Boer, of Vienna, who was so great an advocate for leaving things as much as possible to nature, and for the greatest possible simplicity, was of this opinion. Mad. la Chapelle and Professor Naegele confirm it, and these are the three most experienced names in Europe. In no lying-in hospital in England, Germany, or France, has turning been so successful as in the hands of Madame la Chapelle. One reason in favour of our bringing down both feet is, that where we have brought down only one, the other is liable to stick across the pelvis, and thus become fixed. La Motte relates a case where the child presented with the head, hands, and foot; this last he brought down as far as the knee, but here it became immovable, "although," says he, "I did all I could." He passed his hand up again, and found the other leg fixed against the middle of the left ilium, and, as it were, jammed into the very substance of the uterus; this he disengaged, and, bringing down both feet, the labour terminated easily. This, however, is rare; and Portal recommends, if you cannot bring down both feet, to bring down the foot and leg you have taken hold of first, which, as it comes forwards, the arm which presented recedes, the other foot lying close to the child's belly. It has been supposed by some, that having one leg of the child turned upon its abdomen tended to preserve the cord, and, as far as rendering the passage of the child's body more difficult and gradual, it resembles rather a presentation of the nates, which, as I have before told you, is more favourable to the life of a child than a presentation of the feet. Giffard also mentions, that where the child is not very large and the patient has had children before, there is not a necessity for pulling down both feet, for if one leg presents and the other be bent upon the abdomen, it will easily pass. All this is, doubtless, perfectly true, gentlemen; but still I must declare myself in favour of bringing down both feet, for it has always appeared to me, that the nates of the child did not enter the brim of the pelvis so readily where I had hold of one foot as where I held both; and we may easily imagine this to be the case,

when we recollect, that under these circumstances the child would be pulled unequally.

Where the knees are high and the feet out of reach, it is of the utmost importance that you should distinguish correctly between the knees and the elbows of a child, for, by a superficial observer, they may be very easily mistaken, and this must by all means be avoided. It will be well worth your while, gentlemen, to examine the difference upon a living infant;—if you bend its knee and then feel the joint, you will find that it consists of two prominences (the condyles of the femur) and a depression between them; whereas in the elbow you have the sharp prominence of the olecranon in the middle. This means of diagnosis has served me in several cases of difficult turning, and I am sure you will find it very useful: the size of the arm or thigh is no criterion whatever.

The feet must be held between the fore, middle, and ring fingers, and in bringing them down it must be with the articulation, or, in other words, the child must be turned forwards. As the child turns, the hand upon the outside the abdomen is of great assistance, it assists us to move the body, and, at the same time, prevents the head from flying too suddenly towards the fundus uteri. This is of great importance, for the too sudden movement of its contents will frequently have such an effect upon the uterus as to produce a paralytic or atonic state of this organ, which will sometimes be followed by sudden death. As soon as the head is in the fundus uteri it has become a common foot presentation, and, as such, we ought to treat it, leaving the rest entirely to nature. This, as I before mentioned, Deleurye noticed so particularly, and for this reason I must request you, gentlemen, carefully to bear in mind the distinction which I have drawn between turning the child and bringing it into the world. "In making the turning," says Wigand, "I make a point of doing nothing after I have brought a foot into the vagina, but waiting patiently for the pains I leave the rest to nature; in this way I have observed that when the pains begin to expel the child, they do it with greater power and rapidity than in the most regular labours." In another place, after having brought the feet into the vagina, he says, "I then turn the patient unto her left side and wait for the pains, these sometimes do not return for a whole hour, but then so powerfully and quickly that the child is born in full vigour and activity." Dr. Merriman, in his Synopsis of Difficult Parturition, mentions, that it has been recommended by Dr. W. Hunter to bring the child down by the nates instead of by the feet, from the known fact that nates' presentations are more favourable to the child's life than those of the feet. The authority of such a man deserves much attention, and certainly where it can be done it is desirable. W. J. Schmitt, of Vienna, has also recommended it, but it is evident, where the membranes have been

ruptured some time, and the uterus firmly contracted upon the child, that taking hold of the feet must be much easier, more especially if the child be covered with the vernix caseosa. The grand principle is the same, viz. to conduct the expulsion as gradually as possible; there is no use whatever in hurrying this part of the operation, for if the child be alive we place it in imminent danger of its life, and if it be dead, as will easily be known by the cord not pulsating, we are putting the mother to a great deal of suffering for no reason. "In footing cases (says Dr. Merriman) where compression of the cord by the head is dreaded, the delivery of the body should be very slow, to relax and dilate the part as much as possible." The toes should be always turned backwards, and as the chin comes within reach it must be depressed upon the breast, by placing the first and second finger of the left hand upon each malar bone, and pushing up the occiput with the fingers of the right hand, in this manner the chin passes more quickly over the perinæum, and the cord falls naturally into the hollow of the sacrum, where it is safe; in fact, we should always endeavour to direct the cord towards one of the sacro-iliac synchondroses, more especially the right, because here there is most room when the head is passing; on the other hand, where the chin is over the pubes, or where it, in any other direction, has quitted the breast, the cord is certainly pressed upon, and the child lost.

Turning by bringing down the feet was unknown to the ancients, they considered that the child could only be born with the head first, and therefore tried always to bring down the head; if this did not succeed they had recourse to sharp hooks, and thus brought away the child. It was, I believe, Ætius, a physician of Amida in Mesopotamia, about the beginning of the sixth century, who recommended, if the feet presented, not to push them up and search for the head, but to deliver the child in that position; the operation was first proposed and taught by Pierre Franco in 1561, but it was not brought into notice, or practised, until 1573, by the celebrated French surgeon, Ambrose Paré; his work was afterwards translated into Latin by his pupil, Guillemeau, in 1582, and thus made more known. To Mauriceau, a man of great learning and experience, are we indebted for the operation being brought to a greater degree of perfection, and being better understood, by means of his valuable work, which appeared in 1668, also to De la Motte, a man of remarkable veracity. Mauriceau described chiefly his successful cases, but La Motte candidly mentions also those where he failed, and this is what renders his observations so valuable; hence Haller calls him *homo sincerissimus*, it was he who greatly improved the method of turning, by never trying to push back the presenting part, but passed up his hand along it, knowing that it would recede as he brought down the feet; from the result of his practice the elder Stein

must have turned with great dexterity, also Osiander, and especially, as I have before mentioned to you, Madame La Chapelle.

The next operation, which I have to describe to you for delivering a full grown living fetus, is the *Cæsarean operation*, where, on account of circumstances, which render delivery by the natural passages impossible, the child is brought into the world through an incision made into the abdomen and uterus. When the misproportion between the size of the child and cavity of the pelvis exceeds the degree within which the delivery cannot be effected by the means already treated of, the only means that remains is either by delivering the child through an artificial passage, or by lessening its size by cutting instruments. The *Cæsarean operation*, gentlemen, is the most dangerous operation which exists. Richter, in his Principles of Surgery, says, "in spite of the greatest possible precautions, the result, in by far the greatest number of cases, is unfavourable." Metzger, in his *Medicina Forensis*, says that in fifty cases only one survives, but this is making it appear worse than it really is; still, however, it is a highly dangerous operation. According to Boer, out of fourteen cases only one survives, and Baudelocque says, that out of ten scarcely one recovers; hence we are not authorised to perform it upon a living person, unless it be most distinctly and imperiously indicated, the only case where it is so is where one or other of the pelvic diameters is so contracted as to render it impossible for a full grown fetus to be brought alive into the world by the natural passage; in this case it is the only means of preserving the life both of the mother and the child, but then we must not only feel certain that the child is alive, but that it is also capable of supporting life, before we can conscientiously undertake the operation. This uncertainty as to the life or death of the child greatly increases the difficulty of deciding. Under circumstances, where there is reason to believe that although the child may be alive, it is nevertheless unable to prolong its existence for any time, and the pelvis so narrow that it can only be brought through the natural passage piecemeal, we are certainly not authorised in putting an adult and otherwise healthy mother into such imminent danger of her life, for the sake of a child which is too weak to support existence. Circumstances may nevertheless occur where the pelvis is so narrow, that the child cannot be brought through the natural passage, even piecemeal; in this case, even if the child be dead, the operation becomes unavoidable. Under the above mentioned circumstances (says Richter) it is the duty of the surgeon to perform the operation, and he can do it with the more confidence, from the knowledge of many cases being on record where the operation has succeeded even under very unfavourable circumstances, and where it has been performed very awkwardly; moreover it seems highly probable, that the unfavourable

results of this operation cannot often be attributed to the operation itself but to other circumstances; not unfrequently the uterus has been so bruised, irritated, and injured by the violent and repeated attempts to deliver by turning, or the forceps, and the woman so exhausted and brought into such a spasmodic and feverish state, by the fruitless pains and vehement efforts, together with the anxiety and restlessness which must occur under such circumstances, that it is impossible for the operation to prove successful. Here it is an important rule, that we should decide as soon as possible, as to whether she can be delivered by the natural passages or not, we should allow of no useless and forcible attempts to deliver her, and if these have been made we should carefully examine whether the passages, &c. have been injured, and should proceed to the operation without delay. As I have before told you, gentlemen, it is almost impossible to know with certainty, *before labour*, whether the child be alive or dead; hence, in England, where this operation has been so remarkably unsuccessful, the perforation has been almost always preferred, in fact the *Cæsarean operation* in this country is only indicated where it is impossible *any how* to bring the child away by the natural passages. Dr. Merriman, in his *Synopsis of Difficult Parturition*, has given some interesting details of the result of the various *Cæsarean operations* which have been performed in England during the last twenty years. Of twenty-three cases only two women were saved and eight children, thus out of forty-six lives only ten were saved; although it is no systematic work I consider it as one of the valuable books which have been lately published on the subject.

"On the continent of Europe," says Dr. Dewees, "this operation is resorted to at an early period of labour, before the woman is either exhausted by the continuance of bootless pains, or in a state of almost gangrene from fever; the uterus is cut before it is inflamed, and the child is extracted before it has expired, and the attempt to save both mother and child is sometimes crowned with the happiest result. Is there not, then, strong reason to believe, that were the same independence exercised by the surgeons of Great Britain toward the poor sufferers from deformity, the same fortunate issue would happen as in France or Germany, and as frequently? procrastination is the cause of the evil."

With respect to the directions for performing the operation, these I shall leave for you, gentlemen, to procure from the different works on surgery. It would be of little use my taking up your time by entering upon this subject where I have no observations of my own to offer, and where you can procure all the necessary knowledge much more fully from other sources. The article on the *Cæsarean Operation* in Cooper's *Surgical Dictionary* is well worthy of your attention, for it gives an excellent digest of every thing which is known about it.

The incision has been recommended by various authors to be made in three different ways,—in the linea alba, at the side, viz. at the outer edge of the rectus abdominis muscle, and transversely. The incision in the linea alba is that which has been most commonly used, and the preference in favour of this is supported by the authority of Smellie, Platner, Henkel, Deleurye, Baudelocque, and others. It is recommended by the following reasons:—1st, the abdomen is usually more distended at this point; 2nd, the uterus lies immediately beneath the integuments; 3rd, the intestines are usually pressed towards each side, and therefore when the incision is made on one side they frequently protrude, a circumstance which seldom occurs when it is made in the linea alba, except, perhaps, towards the end of the operation; 4th, in the linea alba we have only to cut through the external integuments in order to reach the uterus, while at the side we have to cut through considerable layers of muscle; 5th, the cicatrix in the linea alba is generally firm and strong, probably from the tendinous nature of the incised parts, hence protrusion and hernia of the intestines occur much less frequently with this than with the cicatrix of an incision made to one side*. The incision to one side has been recommended by Levret, &c., for the purpose of not cutting into the uterus at the spot where the placenta is situated; but it is extremely difficult to ascertain to which side the placenta is fixed, nor are the rules which M. Levret has given for determining this point at all satisfactory. The transverse incision was recommended by M. Lauerjat, of Paris, in 1788, on the grounds that where the patient lies in a bent posture, the transverse incision is more easily closed, and does not need the bloody suture, hence it heals more rapidly; it is considered also to be less liable to be torn open by coughing or vomiting than where the other incisions are made. But the advantages which M. Lauerjat has assigned to this method do not outweigh the disadvantages, and hence it has been scarcely ever practised.

Another mode of operating has been proposed by Professor Ritgen, of Giessen, viz. of making a transverse incision at that point where the peritoneum quits the anterior parietes of the abdomen, and, passing over the fundus of the bladder, is continued upon the anterior wall of the uterus. He proposes to separate the peritoneum as little as possible, and make the incision in that part of the anterior surface of the uterus which is not covered by it; hence we should thus avoid cutting into the cavity of the peritoneum, and exposing the intestines to the action of the external air. All this may be very good in theory, gentlemen, but I need hardly tell you that it will not do in practice. It is of the utmost consequence that the intestines should be exposed to the air for as short a time as

possible; it is well known that they rapidly increase in bulk, partly from inflation and partly from thickening of their parietes, and this greatly diminishes the chances of recovery. "Are not the fatal consequences," says Dr. Hamilton, "rather to be imputed to the access of the air on the irritable viscera? Dr. Monro, of Edinburgh, in making experiments on young small animals, such as bitches, cats, frogs, &c., by opening the cavity of the abdomen, and tying the biliary ducts, remarks, that though a large opening into the abdomen be made by incision, if the wound be quickly closed and stitched, the animal will recover, and no bad consequences follow, but if exposed a few minutes to the air, dreadful pain soon comes on, which the creature expresses by the severest agonies, convulsions at last ensue, and death within four or six hours after the operation. On opening the abdomen after death, the whole viscera are found to be in an inflamed state and universally adhering to one another." Professor Naegele suggests that large sponges dipped in oil should be laid over those convolutions which are exposed to the air during the operation. The condition of the system at this time is peculiarly unfavourable to recovery after such an operation, on account of the discharge of lochia, the secretion of milk, and the disposition to inflammation and exudation which now exists.

I shall not detain you by giving the old and oft repeated case of Jacob Nufer, the pig-gelder of Siegershansen, who first performed this operation on a living woman (and that too with success) in the person of his own wife, A.D. 1500, for you will find a *quantum suff.* of the particulars in almost every systematic work on midwifery, besides a variety of much more interesting and instructive cases among the different medical periodicals. Although the Cæsarean operation has been performed with much greater success on the Continent than in this country, nevertheless the result has been unfavourable in the hands of all the celebrated accoucheurs. Thus, for instance, Stein performed it three times, Baudelocque four times, and Oslander twice, and all terminated fatally. It is usually said that the Cæsarean operation derived its name from Julius Cæsar, who is supposed to have been born in this manner, but it is highly improbable that this was the case, because at the age of 30 Julius Cæsar speaks of his mother as then living. Professor Naegele would rather explain it thus, viz. that some one of the Julian family, which was one of the noblest in Rome, having been born *ex caso matris utero*, had acquired the surname from the operation, not that the operation had taken its name from the family name of Cæsar. The operation itself is of great antiquity, for as early as the time of Numa Pompilius no woman far advanced in pregnancy was allowed to be buried until she had been opened.

Section of the Symphysis Pubis.—I shall conclude this lecture, gentlemen, by giving you a short sketch of the history of an opera-

* Richter.

tion which was once supposed capable of superseding the necessity of the Cæsarean section, and which for a time produced a considerable sensation in the medical world, but which has since fallen into merited disrepute. It had long been a prevailing opinion among many authors, that in difficult labours the bones of the pubes separated from each other, and thus enlarging the pelvic cavity allowed the head to pass. This doctrine had been taught at a very early period by Severin Pineau, viz. in 1639, and also by Petit in his surgical lectures; but it has been since satisfactorily shown, that the antero-posterior diameter, which is that most usually defective in a deformed pelvis, gains nothing by a separation of the pubic bones; this has been shown by Boer and many others. The unfavourable results, and highly dangerous character of the Cæsarean operation, had always excited much attention, and had induced De la Courouee, so early as 1655, to attempt the operation on a poor woman who had died in labour undelivered; but although the result appeared favourable, still it did not seem to excite any further attention until 1768, when Sigault, at that time student of medicine, first proposed this operation to the Academy of Surgery at Paris, as a means of preventing the Cæsarean operation being performed upon a living woman. There can be little doubt but that he got the idea from Pineau's work, or, as Michell asserts, was informed of it by one who had been formerly a pupil of Petit. Dr. Ruffel, who was appointed to examine into the merits of his proposition, gave an unfavourable report, for having made several experiments on dead bodies, he found that the increase of space in the pelvis was so trifling, that no advantage could be expected to be gained in a labour where the narrowness of the pelvis was so great as to indicate the Cæsarean operation. On these grounds the Academy rejected his proposition. Anton Louis, Secretary to the Academy, wrote an account of it to the celebrated Peter Camper, who was pleased with the idea, and repeated the experiments on dead bodies, and on some living pigs, but these animals would not bear the bandage, and although the wounds healed, they remained lame. The notice which Camper had paid the subject encouraged Sigault, although Baudelocque confirmed Ruffel's opinion in 1776.

At length an opportunity presented itself in the case of a deformed woman, the wife of a soldier, named Souchot, at Paris, who had been delivered four times before by Sigault on account of deformed pelvis, where the antero-posterior diameter was said by some to be three, by others to be only two, inches and a half in length, and where the last time he had turned and brought away a dead child in the presence, and with the assistance, of Levret, Dessault, Vicq d'Azir, Coutouly, and others, and where Levret is said to have declared it as his opinion that the pelvis was only two inches and a half from the promontorium sacri to the symphysis pubis, and

that it was impossible to deliver her of a living child without performing the Cæsarean operation. On the 1st of October, 1777, towards evening, Sigault determined on performing the operation of dividing the symphysis; he had no other witness but a physician named Alphonse le Roy, a sworn enemy to Levret, a man who, with the exception of Sigault himself, was most prejudiced in favour of the operation, and one the veracity of whose testimony had long been doubtful to every impartial mind; it seems strange, therefore, that Sigault, who for the last five days before the operation had been well aware that he would have to deliver the patient Souchot, should not have made a point of having more impartial witnesses present. By Sigault's own account he performed the operation in a state of great trepidation, and finished it with a degree of unnecessary and injurious rapidity in five minutes, by the light of a single candle, and without any extraordinary suffering on the part of the patient, although she herself declared that she had suffered most acute pain. The ossa pubis are said to have yielded two inches and a half from each other, during which time Sigault ruptured the membranes and brought down the feet, which le Roy took hold of, and delivered her of a living child.

The woman suffered much from prolapsus of the uterus and vagina, she had incontinence of urine, and walked with great difficulty; these particulars, however, were not mentioned at the time, and it was some while before people were inclined not only to suspect that the child from its remarkable smallness might have been safely delivered without the division of the symphysis, but that in all probability it had of itself very nearly approached to a natural birth.

Le Roy, partly out of spite against Levret, Ruffel, and the other members of the Academy who had opposed the operation, and partly from his well known love of puffing, determined to use his utmost endeavours in blazing it about, and taking his due share of the credit. Sigault presented a report of the operation to the Faculty of Medicine, and requested a commission to examine into the circumstances of it. The patient, who, although the wound was healed, had remained lame, with a constant incontinence of urine, was presented to the Academy of Medicine on Dec. 1st, 1777. A sermon had to be preached on the section of the symphysis pubis, wherein it was extolled as a mercy sent from Heaven. It was published in all the newspapers of the day, and a printed report of the operation had to be sent to all the physicians and surgeons of the provinces, to the king and royal family, the ministers, the foreign ambassadors, and all the nobility of the land. A medal was struck by the Faculty of Medicine to commemorate Sigault, Le Roy, and Souchot; a hundred of these were sent to Sigault, fifty to Le Roy, besides which Sigault and Souchot received a pension from government.

The noise which was made about this operation induced several continental practitioners to repeat it, and from 1777 till 1779 eight sections of the pubes were performed, with the melancholy result that it cost the lives of four women, and of the rest two remained maimed for life; of the eight children, *only one was born alive*, and that very weakly. There is every reason to suppose that at least four of the patients might have been successfully delivered in the natural manner without division of the symphysis; and in the other cases, if the Cæsarean operation had been performed at a sufficiently early period, that *certainly* the children, and in all probability the mothers, might have been saved.

Successing years gave equally unfavourable results. The operation was performed in the most thoughtless manner, and with a degree of cruel violence which deserved the severest censure. The symphysis pubis was divided in cases where the pelvis was thoroughly well formed, and where those women who recovered from the operation were afterwards delivered several times without assistance, and with perfect ease and success; the skin and fat above the pubes were frequently divided, and it was then declared that the section of the pubes had been performed. The operation was frequently performed without even asking the leave of the patient or of her friends, and without having a consultation on the subject with other medical practitioners. It repeatedly happened that after the operation the pelvis, either where the bones had reunited, or after the death of the patient, was found larger than had been at first asserted; and Louis, the secretary of the Academy, mentions a case, where a practitioner had determined to perform the section of the pubes on a woman, the antero-posterior diameter of whose pelvis was affirmed to be only one inch in length; luckily, however, for the patient, whilst the operator was arranging his instruments, a full grown fœtus was born without any assistance.

Reviews.

Diseases of the Spinal Marrow. By R. B. Todd, M.D., Oxon.

THE subject treated upon in the present essay is one which the profession does not, we fear, properly appreciate:—it is one which in our estimation imperatively demands the closest attention, for we believe the spinal marrow to be a powerful source of disease. This opinion is based upon personal experience for some years—upon the facts which have been promulgated by numerous writers within the last ten years, especially by Dr. Brown, in an essay on spinal irritation, and by the very excellent works of Teale, Griffin, &c., who have, by accumulating facts and by attentive observation, established a position which is incontestable, that many anomalous

affections of the abdominal and thoracic viscera are referable to spinal irritation: this they have verified by multiplied examples. Many cases which, prior to the attention being drawn to this topic, were regarded as organic disease—as incurable disease, are now, thanks to the progress of science, discoverable and readily traced during life.

Pain in the side is not now necessarily a sign of consumption, functional derangement of the lungs, organic lesion:—a new aspect they are viewed in; they are, in short, many of them referable to functional aberration of the *spinal marrow* or its *meninges*.

Dr. Todd in his essay has compressed into a small compass the leading facts which have been collected on the subject, and has enriched them with his own judicious observations. He first takes a general survey of the anatomical and physiological conditions of the spinal marrow, and then traces the various morbid changes which it undergoes, in a methodical and philosophical manner.

We shall give the following extracts, as general and fair examples of the mode in which the Doctor has treated the subject:—

“The symptoms which result from inflammation of any portion of the spinal marrow vary according to the region in which the inflamed part exists. In the early stages there will be increased sensibility, more or less pain in the back, muscular spasm, and sometimes convulsion; as disorganisation proceeds, the sensibility becomes blunted, and paralysis of sense and motion ensues; sometimes there is no paralysis, but violent convulsions, and in such cases the fatal result ensues speedily. The progress of the symptoms is proportioned to the activity of the inflammation. Hence in some cases we have a train of obscure premonitory symptoms: pain in the course of particular nerves; formication; feebleness of muscles; sometimes a kind of subletus; deficient action of some internal organs which may be connected with the spinal marrow. If the seat of irritation be in the cervical region, difficulty of deglutition is among these precursory symptoms, and sometimes slight dyspnoea, which may end in complete asphyxia; but there is a remarkable variety as to the extent of the paralysis which follows disease in this region. In some cases it has extended to the four extremities, but in others it was confined to the upper, and in a few instances the paralysis affected the lower extremities only, although the upper part of the cord was most extensively the seat of disease. This fact has been regarded by some physiologists as proving that the several segments of the spinal marrow are independent of each other; though it is obvious that, if we admit the justice of this inference, a difficulty, perhaps as hard to be surmounted, will arise to account for the occurrence of paralysis from a lesion precisely similar in locality, extent, and nature. It is well known that the division of the spinal marrow in the neck of an animal leaves his four extremities

powerless; and that the dislocated cervical vertebra which so compresses the marrow as, if we may so speak, to stop the nervous current downwards, paralyses every part below it. Have we not, then, as much reason to infer from these facts, that the inferior-ports of the marrow are dependent on the superior, as to suppose them independent, merely from the occurrence of a few such cases as those we have alluded to? In the present state of our knowledge as to the connexion of the brain and spinal marrow, and their influences on each other, and on the organs of motion and sensibility, we are not authorised to form conclusions from data which, to say the least, are not completely established."

"*Treatment.*—There is no reason why inflammation of the spinal marrow should not be cured, but it is so very seldom met with in the first stage, that the practitioner has always to labour at a great disadvantage. In the treatment of inflammation of the spinal marrow, the antiphlogistic system must be rigidly observed; general and topical bleeding, with counter-irritation from blisters or stimulants of various kinds. Issues or setons are to be employed if the inflammation be of the chronic form. The tepid or the cold douche applied from a great height to the suspected region, has been known to be very serviceable.

"In the chronic stage we may expect to confer some benefit by the application of remedies. Perfect rest in the horizontal posture is, perhaps, the most necessary and useful measure, to which we may add the adoption of means to keep up a continued counter-irritation. Close attention to the digestive organs, a continued course of purgatives, combined with a mercurial, tepid or cold bathing, or the douche, will often be found useful. The strychnine, too, may be administered either internally or to a blistered surface through the medium of the skin.

"The effects of concussion of the spinal marrow seem to depend very much upon chronic inflammation. Concussion sometimes proves immediately fatal, probably in consequence of the altered circulation about the spine and the general shock to the nervous system, but in general no morbid appearances can be detected. It is possible that acute inflammation may follow concussion, but more frequently there are all the signs and symptoms of chronic inflammation, which in some instances disappear without any bad consequences. At other times the concussion is followed by some permanently morbid state of the cord, which causes permanent paralysis. Sometimes these symptoms continue from the moment of the accident, but at others the patient is taken up powerless, he recovers, and in a short time gradually relapses into a worse state. General paralysis has not uncommonly succeeded to this accident."

These two specimens will serve to accomplish the objects we have in view. They show Dr. Todd to be a fair and candid reasoner,

who draws his inferences from acknowledged and palpable data, and is seldom if ever led astray by the speculations of the theorist, or indulges in the wranglings of casuistry. We heartily recommend this treatise to the practitioner.

An Essay on the Tuberculous Diseases of the Bronchial Glands.—Prize Essay. By J. M. BERTON.

It has, for a long period, been a question with pathologists, whether or not there be lymphatic glands in the substance of the pulmonary tissue. The position has been affirmed by speculatists who never witnessed their existence, and negatived by casuists who never investigated the question. The history of *absurd doctrines in medicine* from the days of Hippocrates to the present century, would afford a most curious and a most interesting theme; for the exposure of errors is frequently the first step to the discovery of truth.

There was a notorious individual, though a clever one, who affirmed with the most unblushing effrontery, that phthisis was but tuberculous disease of the pulmonary glands—disease of structures which are really not in existence, and upon which sandy foundation he erected a very pretty little theory, but like all other such edifices, the first wave washed it away, and buried it in the abyss of the ocean.

One and the great object of the present essay is, to develop the various morbid changes to which the bronchial glands are liable. The author commences with a brief exposition of their anatomical relations, stating that they are situated around the bronchii, from the tracheal bifurcation into the very tissue of the lungs; and agrees with Haller that they are analogous in their structure and functions to other lymphatic glands; that they receive the lymphatic vessels from the lungs, heart, and the inner surface of the thoracic walls: being reddish in the young, brown before the middle period of life; and dark or black in old age—from it is presumed the absorption of carbon in the lungs. These structures may be affected with the diseases peculiar to their own system, or be implicated in those of the lungs. He states that those glands are more frequently diseased in infancy than in later periods; that they are subject to inflammation, which is usually chronic in its character, slow in its progress, and seldom terminates in suppuration;—this inflammatory condition is evinced by many of the symptoms of phthisis. Every cause which may produce irritability of the system predisposes them to disease. He has never met with a case of suppuration of those glands. Laennec asserts that he has met with but a *very small number*. He contrasts the number of cases of what he designates *bronchial phthisis*, in town and country—in the former they greatly pre-

ponderate. Children living in towns, and those who breathe the polluted air of hospitals, or who live in damp situations, are the most prone to enlargement of the bronchial glands.

In corroboration of those structures being converted into tuberculous tissues, he adduces the tubercles forming in the cervical glands in children during dentition, ophthalmia, &c.; the mesenteric glands becoming alike disorganised in cases of inflammation or other diseases of the bowels. "In like manner, in children, the bronchial glands inflame, and are transformed into tubercles after prolonged pneumonia or bronchitis."

The subject is one which really is little known in England. The author establishes beyond a criticism the following positions, from an experience on a large scale—from personal knowledge of numerous cases during life, and *post mortem* appearances,—that in all cases in children where there had existed thoracic inflammation the bronchial glands were disorganised to an extent in a ratio to the continuance of the disease. That when pulmonary affection had been but of short duration, the bronchial glands presented the following appearances: they were of a redder colour, were shining, and enlarged in size; that when the disease had existed for a longer period they had, in addition, tuberculous matter in their substance; and, lastly, in very protracted cases, the normal tissue of the gland seemed entirely removed, and its place occupied by tuberculous formation. These facts afforded the author interesting phenomena, inasmuch as they displayed the partial, the gradual, and the complete conversion of these conglomerate glands into tubercle; and they evinced, further, the substantive proof, that tubercles, if not the consequence—the very products of inflammation, were very closely allied to that particular condition. The characters of the natural and morbid structures are very lucidly depicted, and the line of demarcation between them in the second stage graphically defined and judiciously commented upon.

He next gives a table, showing the very close connexion between diseased bronchial glands and pneumonia, bronchitis, pleurisy, and phthisis, showing, most satisfactorily, that in all the latter affections those glands partake, and this in proportion to the extent of the ravages. He endeavours to prove that the signs of enlarged and tuberculous glands are obscure; that sometimes, when they become softened, ulceration takes place through the walls of the bronchii, and the matter is in this manner expectorated, giving, occasionally, evidences of pectoriloquy; not, however, frequently, for pectoriloquy in children is of rare occurrence. A number of cases are presented, showing perforation of the bronchii, œsophagus, and pulmonary artery, by matter from the bronchial glands. The following case will afford an example of the character of this disease.

"OBSERVATION III.—*Perforation of a Bronchus and the Œsophagus.*—Moreau, a girl, aged six years, admitted into hospital July 24th. She was always liable to take cold; the glands of the neck were engorged; she had a cough of several months' standing, but never kept her bed until eight days before admission. From that time she had much cough, fever, headach, and occasional vomiting.

"She presented the following appearance and symptoms:—Gangrenous state of the mouth (*stomatite gangreneuse*); pulse 120; some diarrhœa; frequent cough; no expectoration; muco-crepitating râle at the right side; slight dulness posteriorly at the same side. She died on the 14th August following.

"*Post Mortem.*—Adhesions of the pleura at the two inferior thirds of the right lung; some adhesions also at the left side. The superior lobe of the right lung posteriorly was found in a state of grey hepatisation. The mucous membrane of the trachea and of the bronchii was generally pale. On the left branches, half an inch from the bifurcation of the trachea, was a round perforation, half a line in diameter, communicating with another perforation lengthened from above downwards, having smooth pale edges, and situated in the œsophagus. This latter was a line and a half in extent, and two lines higher up than the preceding one; the communication between them was by means of an intermediate cyst, formed of resisting fibrous tissue; its internal surface was of a reddish brown colour. This cyst, the diameter of which might be considered at three or four lines in extent, had apparently belonged to a degenerated bronchial ganglion, whose softened tuberculous matter had escaped by the accidental openings we have remarked. The greater number of the other bronchial glands were slightly hypertrophied, and of a deep red; several of them were partly tuberculous. The subject of this observation had been ill eight months before admission, and had cough and vomiting. Could the perforations above described, the borders of which presented no traces of recent inflammation, have had their origin at the above named period?"

With respect to the treatment of such cases little is said. If the disease be recognised, and as it is always concomitant with pulmonary disturbance, the usual and appropriate measures are to be employed.

How such diseases of the bronchial glands should originate may be fairly assumed. Irritation in the foot will often create enlargement, inflammation, &c., of the *vertical* inguinal glands; the same will arise from irritation on the genitals in the transverse series of glands; in the axillary glands, from irritation in the arm; in the mesenteric, from disorder of the bowels—why not in the bronchial glands from disease of the lungs? The essay is an instructive one, and therefore worthy of perusal.

Medico-Chirurgical Review, April, 1835. . .
Medical Quarterly Review, April, 1835.

It must be obvious to every medical reader that the weekly journals are ever in advance of all others in the newness of their matter, medical or general,—this is natural; they contain every thing as it appears, and we humble individuals have the (not vanity) to believe that every thing new under the sun is brought the earliest in our journal before the public, it is at any rate our urgent desire to do so,—that we accomplish this we believe,—that we are anticipated by our contemporaries in any thing great or important we have no hesitation in denying. Our politics are liberal, our comments on new works, or new ideas are conducted with that fairness which ever characterises liberal minds, and every other topic must claim the warmest commendation. The two journals before us are both excellent of the kind, they contain many elaborate reviews, some of them finished,—reviews which give the very pith and marrow of the works reviewed, and they give the spirit of medical literature of the tri-monthly period in a very fair and satisfactory manner. They are, however, we must confess as honest journalists, deficient in the very important requisite of our Edinburgh contemporary in those materials which it is so eminently furnished, viz.—need we state the essays from the *Medico-Chirurgical Society*? We do trust that the *Royal Medical and Chirurgical Society* of London, with its blushing title, and the talent it contains, and the liberality of many of its members will, instead of publishing occasional reports of transactions, permit the various journals, not one but all, the full liberty, their full accordance to send to the world those discoveries, those doctrines which, owing to the rapid progress of medicine, must involuntarily emanate from that society. In good humour and kindness we suggest this, it would redound not less to their philanthropy than to their liberality to do so. They would be conferring a large boon on the profession and on the public. Some of their articles may be laid under contribution in our next number.

—
The Edinburgh Medical and Surgical Journal, April.

In the *Edinburgh Journal* of the present month we find some cases so apposite to the subject we have been discussing in the *Essay of Berton's*, that we feel it necessary at the same moment to allude to them; and the first article we shall advert to is one by Dr. Christison, and when we say this there is not perhaps an individual in the profession who will not respond his approbation to the excellency of that physician. To accumulate facts and to record them require no other qualities than those of patient observation and great industry, to generalise the facts thus adduced, and to deliver them before an acute profes-

sional ordeal, demand a mind of a higher cast; the positive philosophic mind, if we may employ the phrase, deals not in details but in principles, he glances at the facts but forgets not the principle. Nature has constituted the mind in a singular manner, she has made it a chaos of inconsistencies, here it exhibits a wildness of exuberance, there a barren soil, there fertile in brambles and bulrushes, now a scene of all that the judgment could desire, or that the imagination could aspire to. This is a digression. Let us leave the topic to abler commentators.

Case of Empyema and Pulmonary Tubercles, illustrative of the Connexion between Tubercular Deposition and Chronic Inflammation.

BY ROBERT CHRISTISON, M. D.

The subject of this case was a girl, about 6 years of age, who, after scarlet fever, was attacked with a pulmonary affection, she exhibited the indications of chronic pleurisy and subsequently of empyema, was tapped twice for hydrothorax. The attack of scarlet fever was accompanied by a cough, which was but slight, but at the termination of a fortnight the symptoms of what appears obvious was an attack of pericarditis, there was pain at the left side of the sternum; great difficulty of breathing; cough more troublesome; frequent perspirations; scanty urine, &c. After eight weeks she was attacked with distinct pleuritic effusion of the right side, where great dullness was indicated on percussion. The left side exhibited also some signs of aberration. The right side showed in every part the entireness of respiration, but more feeble than natural, so that it was presumed the sound arose from an increased bronchial respiration of the left side, which was transmitted through the accumulated fluid.

The constitutional symptoms were urgent, hectic having completely set in with its endless train of distressing attendants. Local applications, diuretics, and expectorants having failed, and the dyspnoea becoming more harassing, the chance of puncture was taken advantage of. After twenty ounces had been withdrawn, and the aperture was closed by a compress and bandage, considerable relief was experienced, the right side became of equal circumference with the left, and respiration became audible in the upper fourth of the empyematic side. On the second day improvement was still going on in that side, the sound on percussion becoming pretty clear in the superior region. The disease, however, soon returned to its former state, and the constitutional disturbance was manifestly much increased.

It being the opinion of the Doctor, that the girl evidently could not survive above a day without the most decisive measures being resorted to, he again punctured the chest. Twenty ounces of thinner pus were drawn off,

which again rendered her condition more easy and supportable for a day or two. This, however, was but temporary, for all the previous symptoms returned, and four days after the operation she expired.

Inspectio cadaveris.—The lung in the upper fourth of the anterior part of the chest was crepitant and pervious to the air. Below, however, it was greatly compressed, and contained partly pus and partly coagulated blood. The entire lung was bound down by a membrane of old coagulable lymph, thrown out from the pleura. Much serum, with lymph flakes, were found in the left pleura. A large quantity of thickly studded tubercles, smaller in size than a lentil, occupied the whole of the left lung. So also the upper part of the right lung presented the same appearance,—was not compressed. No softening was discovered in any of the tubercular masses; the condensed flattened portion of the left lung was wholly destitute of the tubercular deposition, and seemed perfectly healthy; the serous membrane of the abdomen presented a healthy appearance, no effusion being found in its cavity. From the history of the foregoing case two points of interest present themselves. In the first place, there was evidently tubercular deposition occurring in connexion with chronic inflammatory action. The former being in all probability deposited during the prevalence of the latter; and, from the facts supplied by this case, it is not an unnatural conclusion to arrive at, (an opinion which is daily gaining ground among pathologists,) that tubercular effusion sometimes originates in chronic inflammation, being one of its terminations in persons of unsound constitution. In the second place, the appearances illustrate very well the effect of uniform pressure on an internal organ in preventing the progress of disease in its texture.

The next is a case of

Tubercular Deposition of the Lungs terminating fatally, without proceeding to Softening.

BY DAVID CRAIGIE, M.D., F.R.S.E.

J. H. æt. 22, a young man rather stout, and of swarthy complexion, had been in the enjoyment of good health, till the twenty-first year of his age.

In the beginning of January, 1827, he became occasionally subject to wandering pains in the sides, with a tickling cough, and difficulty of breathing, on making any muscular exertion. His pulse was at this time about 90, varying, however, sometimes to 100. Mere mucus only was expectorated, and that, too, not very opaque.

Notwithstanding medical treatment, his symptoms became aggravated. His pulse, never below 90, continue to vary from 96 to 100. The pains of the chest, which were principally felt in the left side, became more frequent, as also did the cough, and the expectoration of mucus more copious, but the patient's most constant complaint was of a

craving vacuity, referred to the region of the stomach. Till within six weeks, however, of his death, he did not abandon his usual pursuits.

About the middle of August, the rapid confirmation of his bad symptoms confined him entirely to the house, but, up to the 27th of September, he continued much in the same state, with only an occasional diarrhoea and a slight increase of night and morning sweats, to which, from the commencement of his disease, he had been subject. On the 28th his respiration became so difficult and laborious, as to oblige him to relinquish the horizontal posture. At the same time, his countenance was indicative of much anxiety, was very livid, as were also his lips and nails, and the pulse had risen to 120, being likewise intermittent. On the 1st of October death closed the scene of his sufferings.

The treatment adopted in this case was prompt and decisive. General and local bleeding, antimonials with opiates, blisters, and tartar emetic ointment, were among the first and most energetic remedial agents. Laxatives presided over the bowels, whilst tincture of foxglove was administered to promote the secretion of urine, and at the same time with a view of diminishing the heart's action. Throughout the disease, the matter expectorated, though carefully watched, was never found to be opaque or puriform, neither did it ever sink in the water in which it was discharged.

Post Mortem Appearances.—On raising the sternum, it was observed that the right lung was occupied by minute indurated bodies, especially towards its superior portion, which was also condensed, inelastic, and uncrepitating. The substance of the superior portion of the same, with the exception of being rather more solid than usual, did not present any thing very remarkable. The inferior half was perfectly firm and consolidated, like a portion of liver, of a deep red brown colour, some portions being almost black, and was divided from the superior portion of the lung by a transverse line, very accurate and well-marked. The pleura pulmonalis in different situations presented considerable adhesions.

The tubercular bodies were small and in minute masses, and presented an irregular shape. Not one of them had proceeded to softening, and in no part of the lung or the larger bronchi, could a particle of purulent matter be recognised. Throughout almost the whole of the left lung were sprinkled hard granular bodies. Its substance at the same time being inelastic, condensed, and uncrepitating, though not so much so as that of the right lung. Neither in its bronchial ramifications was there any trace of puriform matter. The heart presented nothing strikingly morbid. The liver was loaded with much dark-coloured blood, but its substance was not preternaturally large or hard. The stomach was a little shrunk, and exhibited some vascularity towards its cardiac portion,

its rugæ being less distinct than in ordinary cases. The intestines were generally healthy.

The remarkable circumstances characterising the above case, is that the lungs presented no tubercular excavations, and consequently, that throughout the disease, no puriform or tubercular expectoration took place; and, as Dr. Craigie remarks, the whole affection of the chest appears to have been more of the nature of chronic peripneumony, than of common tubercular phthisis.

Indeed its progress was marked by less emaciation and debility of the muscular system, than are usually the offspring of the latter disease, wherein the tubercular deposition undergoes the process of softening.

The Doctor terminates the history of the case by observing that the tubercular deposit with the consolidation, and other marks of inflammation of the lung, may be conceived to indicate that the former is the effect of the latter, and, in consequence, proposes the following question.

“Whether there be not reason to believe that in similar cases the tubercular deposition pre-existed, and operated as a predisponent cause to the production and maintenance of the chronic peripneumonic disorder, and its usual effects?”

FOREIGN MEDICAL LITERATURE.

Memoir on the Configuration of the Brain of Man and of Mammiferous Animals. Read at the Royal Academy of Medicine, 7th March, 1835,

BY M. LEURET.

ANATOMISTS long believed, and a great many of them still believe, that there exists no regularity in the number and direction of the cerebral circumvolutions of man, and even amongst encephalotomists, one of them only, Roland, has described and represented them with any thing like accuracy. Those of animals have been even less studied. Gall, who has designed many more skulls than brains, while assigning to the circumvolutions very distinct functions, altogether neglects their anatomy. Vimont, the disciple of Gall, has shown so little fidelity in his designs of them, as to give to the Sylvian fissure of the brain of man, for example, 120 millimetres in length to the right, and 30 to the left side, a difference which nature never yet made. Nor are the plates of M. Serres by any means satisfactory on the point. M. Tiedemann is, perhaps, the only one who has given a faithful representation of the brain of the mammiferous tribe, but without making the deductions from it, to which a profounder research has led me.

The brain of all mammiferous animals, except the class of ruminators, has a determinate number of circumvolutions, the same in the same species, and their general direction the same of whatever species or class they may be; those to the right are found also on

the left, with slight differences, which differences themselves are almost invariably the same. In man, the elephant, and the ape there is no such general uniformity, their cerebral circumvolutions are altogether *sui generis*. In man they are constant and well defined, varying only in detail; in the elephant, if I may judge from the only example I have yet had an opportunity of studying, they are very analogous to, if not exactly like, those of man; in the ape also they are found, but with the same difference of perfection as between the external conformation of that animal and that of man. Then, if what I have advanced be true, that there is exact conformity of brain in all the mammalia tribe, an example of one of the simplest conformation will best illustrate it.

The fox presents an instance of extreme simplicity in his cerebral circumvolutions; four form the exterior surface, clearly separate from each other and superposed; the most exterior very small, bent back on itself, forming by the bend the fissure of Sylvius, above that a longer and larger, a third and a fourth, this last forms the posterior and superior ridge of the lobe or fold; no depression in the first; a slight furrow in the second; in the third a depression in the hinder part, indicating a beginning of separation; a depression in the fourth, and anteriorly a deep furrow. These four circumvolutions are united before and behind; immediately in front there is besides a small triangular circumvolution partly covered by the olfactory nerve, but nothing more is observable externally.

On separating the two lobes, raising the cerebellum, and dividing the corpus callosum, and all the mediant subjacent parts, a pyriform eminence is seen below and behind, which, at an elevation rather short of the posterior ridge of the corpus callosum, terminates in two prolongations; the one external and above, forming the fourth circumvolution already named; the other internal and below, covers the corpus callosum, forms the anterior point of the brain, and bends back to the level of the inter-crossings of the optic nerves: these two prolongations unite in front, and are separated in the middle and behind by a deep furrow. Thus, four circumvolutions on the convex surface, one in front and one within, constitute the whole cerebral periphery of the fox. Very nearly the same simplicity of conformation is found in the dog, wolf, bear, coati, otter, cat, panther, hyæna, and lion; the fundamental principle of it being always the same, the shades of difference very slight. With the herbivorous and ruminating class, the circumvolutions have a special character; they are undulated, not readily distinguishable, do not bend back on themselves, are more spreading, their extremities widening asunder as they advance; whilst the reverse is the case with the carnivorous; the wild boar, hog, and peccary, present the transition between those two classes.

In the brain of carnivorous animals the divisions increase in proportion as it enlarges; thus the brain of a wolf is more divided than that of a fox, of a full-grown fox more than that of a little one; not so with the herbivorous tribe; the brain of an ox has no more divisions than that of a sheep which is of less volume, and it has fewer divisions than that of a horse which is of equal volume. As to the internal circumvolution which, originating behind the corpus callosum, passes over it to the anterior point of the brain, in the fox it is integral, but divided in the dog and wolf; with the herbivorous it is double in the two posterior tiers of its extension, treble in the anterior tier, forming in front of the corpus callosum a cerebral mass of considerable size. Two important considerations here arise—

1st. At the point where the internal circumvolution continues itself with that of the superior external, a *diverticulum* is formed, which in man is called by phrenologists the *organ of reneration*; this organ then is found in all the mammalia that have circumvolutions.

2nd. At the most extreme posterior point of this circumvolution we find it rising to the upper part of the lobe, thus placing itself between this venerated organ and the posterior lobe of the brain. This disposition, rudimentary in the rest of the mammalia genus, acquires a certain development in the ape, and complete development in the elephant and in man, and forms for the internal part of the lobe a kind of repetition, the complement of the transverse circumvolutions which remain to be described.

In almost all the mammalia the same circumvolutions extend from the anterior to the posterior part of the brain without interruption; but in the ape, the elephant, and in man, this continuity is solved. From the anterior margin of the great Sylvian fissure several circumvolutions arise, which, bearing upwards and backwards as far as the middle large fissure of the brain, cut the others across and divide them into anterior and posterior circumvolutions. Three of these transverse circumvolutions are commonly found in man; three also I found in the elephant I examined; the ape has ordinarily one only, but sometimes two.

From the foregoing facts it appears that the circumvolutions of the brain of the mammalia may be divided into three groups; those of man, the elephant, and the ape into four; with the additional circumvolution to all, passing over the olfactory nerve, and ordinarily found integral in the carnivorous class, but divided in man and the herbivorous, and which, from its position, I shall call the sub-orbitaly.

The first group is composed of the two most external circumvolutions, and properly, therefore, may be called the *external circumvolutions*; the second, of the two circumvolutions superposed on the first, which I shall name *medial circumvolutions*; and the third group

of the circumvolution, single or otherwise, found above the corpus callosum, *internal*, but with reference to man, the elephant, and the ape, *transverse circumvolutions**.

But how will phrenologists approve of these facts? The organs which, according to them, indicate philosophy, learning, and science, are, alas! ever found in the sheep, the ox, the goat, the horse, and the ass! An English phrenologist, Mr. Holm, much puzzled on finding in the brain of a cat the *organ of individuality*, began to suspect that, *perhaps*, that organ had *there* some other use. This was a very prudent *perhaps*, and may be found most available in phrenological research.

And as well with the posterior as with the anterior portion of the brain have these philosophers made havoc. Here we find the organs of courage, of theft, and of ferocity; the poor sheep then, having circumvolutions analogous to those of the wolf, ought, in strict phrenological propriety, to have a tolerable inclination to theft, with courage and carnivorous propensities enormous; and the transverse circumvolutions, peculiar, as we have stated, to man, the elephant, and the ape, are happily twisted into organs of resolution, of conscientiousness, and hope. But of what avail are all these fantasticalities, and whence do they arise?—From the study, I apprehend, of skulls rather than of brains, and from the credulity of ignorance and folly: it is also much easier and more convenient to believe than to verify. Yet, even had skulls only been really and thoroughly studied, something might have been gained, some error rectified. To the strong lateral development of the skull of the rabbit, the same as that of the carnivorous tribe, what says phrenology? The skull of the dolphin, rising to a point with a transverse diameter of 148 millimetres by 93 antero-posterior, no doubt indicates fanaticism and cruelty, and ought to be the skull of an inquisitor, not of the creature surnamed by the elder Pliny “the children’s friend.”

But I do not propose to enter further into the details of phrenology. If I have demonstrated the analogy of cerebral conformation between animals differing widely in instinct and faculty—if I have clearly shown that the same parts exist in all of them, I have nearly established the certainty that each of these parts cannot have distinct and special functions, and that, consequently, the phrenological doctrine is utterly without foundation. It however by no means follows that there is no relation between

* To verify the constancy of these general dispositions, it is expedient to use the precaution pointed out by M. Leuret, namely, to harden in alcohol or other means the brain intended for examination, stripped of its *pia mater*; the circumvolutions then separate easily, each group becoming distinct, and there is no risk of mistaking slight depressions for real divisions.—N. du R.

the cerebral conformation and the instinctive, intellectual, and moral faculties; but that relation is yet to be discovered.

Analysis of a Memoir on the Chlorides of the Oxide of Sodium or Calcium employed in Burns. Read at the Academy of Sciences, March 16, 1835.

BY M. LISFRANC, SURGEON TO LA PITIE.

The number of medicaments in use for burns is immense, a simple enumeration of them even would press too hardly on the complaisance of the Academy; I will therefore only recal the fact, that the cure of burns has almost always been an operation of time and difficulty, and that medical men have hitherto frequently considered them mortal, if of extensive surface, even when not deep.

In the year 1825 I tried a new species of medicament for the purpose, and the Academy will judge whether the results obtained are advantageous. My method of treatment has already been many times published in the scientific journals, also in some modern works, has been commented upon, misunderstood, and rendered confused and obscure, in spite of all the pains I had taken to elucidate the matter in my clinics at the Hôpital de la Pitié; in short, the chlorides of the oxide of sodium or of calcium have been denominated *quack nostrums*; but abuse is no argument against its use; and, when the power of a medicament is not understood, ignorantly or injudiciously managed, danger may result; a recapitulation of facts may therefore prove not unimportant.

The chlorides of the oxides of sodium or of calcium are astringent and sedative; they not only prevent the increase of inflammation but dissipate it entirely, and, in the course of a few hours after their application, the sufferings arising from the enervated state of the patient are considerably lessened, sometimes the effect is immediate.

When there is solution of continuity without scab, the chlorides are eminently efficient, as they cause an immediate plastic exudation, which, forming itself over the surface of the wound, in a short time closes the solution: this new tissue commonly develops itself from the circumference to the centre. And not only do the chlorides thus operate in cases of comparatively slight injury, but when it is excessive, when the scabs have fallen and the fleshy pimples are strongly developed. Further, it is important to notice, that a cicatrix thus formed is more solid than when it is obtained by other means. Consequently, should there be ulceration in the lower part of the leg, the integuments cannot become too much tightened, or drawn by the contraction of the muscles; and, as my experience has often demonstrated, this mode of cicatrization resists greatly the progress of the cure. Besides, when the cicatrix is formed, there is still, we know, to work its better organisation; and

that, in proportion as it dries, so does it contract. The contraction of those formed by the action of the chlorides is not so great.

It has been asserted, that the chlorides, from whatever cause, greatly facilitate the fall of the scabs; this is a gross error. Facts demonstrate that if the inflammation is great and phlegmonous, the chlorides augment it almost always; and thus baffle their proposed use; if on the contrary, the phlegmasia is slight, the chlorides lessen it too much, and the work of elimination is retarded—particularly with individuals of spare habit, and where the scab is hard and dry. In truth, the chlorides are rather hurtful than useful when the gangrene proceeds from excess of inflammation, and when, despite of the death of a certain extension of the tissue, the phlegmasia still continues to a high degree.

The chlorides succeed most especially in the first and second degrees of burns. When we first began to employ this medicament we doubted much its use in intense inflammation; but experience has proved that it is not less efficacious when the phlegmasia is only superficial. We should not have sufficiently insisted on its value with respect to scabs, if we had not observed that in the other degrees of burns this medicament, employed before the phlegmasia becomes intense, diminishes the pain and inflammation;—a remarkable case in proof of this may now be seen at the Hôpital de la Pitié.

It is said that art consists entirely in details; never was truth more certain, nor more certainly felt by all who have cultivated surgery with success. Were we empirically to boast of our medicament as a sovereign specific against burns, without indicating, both generally and particularly, its degrees of power and use, we should put into the hands of our brethren (and that has happened) a weapon which not only would often prove useless, but sometimes dangerous.

The chlorides in general use are at three degrees by the chlorometer of M. Gay Lussac; but in the inflammation and the idiosyncrasy of the skin there is great variety. If the chloride, at the degree named, produce no sensation, it is not sufficiently active, and must be raised to four, five, and sometimes even to six degrees. But if the application of the chloride determines a pruritis and painful heat, lasting more than a quarter of an hour, the medicament has too much energy, and may augment the inflammation; the apparatus must therefore be removed, and the degree lowered to two, or perhaps one. The desired effect can never be produced if the pruritis and heat which the chloride occasions are prolonged beyond five, ten, or fifteen minutes.

In our first trials of the medicament we applied it to all the suffering parts, whether denuded of skin or not; and we quickly perceived, that where the rete mucosum was laid bare, there the cure was quickest, and, consequently, that the epidermis checked the activity of the chloride; hence the utility of clear-

ing it away as much as possible, which may be done and scarcely any pain determined, by using precautions quite superfluous to mention here.

A sieve-like compress, spread with the cerate of Galen, is applied all over the surface of the burn, and surmounted by a mass of lint, two inches thick at least, and saturated with chlorine, over which are adjusted dry compresses, and the whole covered with a suitable bandage.

In winter, if the burn is of extensive surface, and the stupor of the patient very decided, the perforated compress must be warmed before it is applied; and in every case when the burn is large, care must be taken to dress it by degrees; according to the temperature of the atmosphere, the bandages, &c., must be wetted with the chloride six or eight times a day at the degree indicated, and the dressing renewed every twenty-four hours.

The use of the chlorides of oxide of sodium, or of calcium, as a medicament for burns, was first suggested to me by the following circumstance:—

The patients were covered with burns of the first and second degree; at least two thirds of the whole surface of the integuments. The first day I followed the precepts recommended by surgery. I opened the blisters formed at their most inferior part, and applied the perforated compress with Goulard ointment, with lint above it. The following day the inflammation had increased to intensity; already the reaction had taken place on the intestinal canal; the patients were drowsy, and gave every other indication of the whole economy being profoundly affected, and, according to the opinion of some practitioners who have written lately on burns, they were doomed almost to certain death. It was at this moment that recollecting the success I had obtained with the chlorides in the treatment of ulcers, I determined to try their effect on these unhappy patients; I did so, and my success was complete.

It is verified by observation that death may ensue from burns of the first degree covering the whole surface of the integuments; but no fatal termination has occurred to my experience from burns of any degree since I have employed the chlorides as a medicament.

From the foregoing statements it results,—

1st. That the chlorides of oxide of sodium or of calcium, employed according to the directions stated, completely relieve the pain, lessen the inflammation and enervation, and prevent reaction on the system.

2ndly. That the chlorides cure more promptly.

3rdly. That they facilitate the fall of the scab.

4thly. That they cause the most advantageous cicatrisation.

5thly. That they often obtain the cure of patients doomed to certain death, if the usual means of cure had been employed.

Analysis of four Memoirs read at the Institute of France.

BY M. VELPEAU.

At the meeting of the Institute, March 16th, M. Velpeau presented four memoirs, one on acute diseases of the throat, especially inflammation of the tonsils; another on inflammation of the mouth, caused by pinching a portion of the gum between the molares; the third on burns; and the fourth on the diseases of the lymphatic vessels.

Angina Tonsillarum.—The object of M. Velpeau's first memoir is to demonstrate that powdered alum, applied by the finger to the part affected, very seldom fails to cure acute inflammation of the throat in a few days. The efficacy of this remedy, says the author, is as marvellous as it is rapid. Employed the first, second, third, or fourth day, while there is yet no abscess in the tonsils, it arrests all symptoms, as it were, by enchantment; the fever abates, the swelling diminishes, the appetite returns, and the convalescence is quickly decided and complete.

Alum had already been in use for certain disorders of the throat; in malignant inflammation, for example, then in chronic; but as the greater number of practitioners remained fixed in opinion that it must be dangerous in common inflammations, its use was not so extensive as it deserved to be. By showing that this remedy is as powerful in simple inflammation as in inflammation of the tonsils, M. Velpeau hopes that practitioners will no longer hesitate to make proof of its efficacy, and rescue thereby hundreds of human beings from the grave.

Inflammation of the Mouth caused by Pinching a portion of the Gum between the Molares.

—In the second memoir, M. Velpeau treats on a malady not hitherto described, though frequent enough, and the cure of which is alum also. It is an inflammation commonly very acute in the internal front of the cheek, quite at the bottom of the mouth, and very soon accompanied by swelling, pain, and throbbing in the neighbouring parts, impossibility of extending the jaws, foetid breath, and sometimes fever. The cause of it is found in the pinching or chewing, as it were, a small portion of the mucous membrane which intrudes itself between the molares. The usual treatment by emollients, bleedings, &c., may prolong the evil indefinitely; but by the aid of powdered alum, the cure is effected in the course of three or four days. As in the case of inflammation of the tonsils, all that is necessary is, to touch the surface of the affected part with the alum morning and night.

Treatment of Burns.—In the third memoir, the author shows that each proposed remedy for burns bears only on a certain degree of

the malady; that cold water and resolatives, for example, good in the first degree, are of no avail in the third or in the fourth degree; that the solution of chloride of lime, of soda, about which some surgeons take to themselves no small praise, are, in fact, of no more real efficacy than cold water, or the solution of the extract of lead, but that a remedy of decided and equal efficacy in the four first degrees of the malady may be found in the dressings of gum diachylon.

M. Velpeau affirms that with this dressing, renewed only every third day, burns of the first degree are cured immediately; those of the second, in four or six days; those of the third, in eight or fifteen days; and those of the fourth degree, in from fifteen to thirty days: the cicatrix is formed by dessication from a number of points at once, not one after the other, or from the circumference to the centre, as is the case under the influence of all the other medications.

Maladies of the Lymphatic Vessels.—M. Velpeau's fourth memoir is part of a large work on the Maladies of the Lymphatic System. The author's observations have led him to results which appear to him important in regard to pathology and therapeutics. Thus he has found that inflammation of the lymphatic vessels having almost always been confounded with erysipelas, inflammation of the veins, and some other phlegmatic obstructions, caused the uncertainty which still exists with reference to the treatment of these latter affections, as that suitable to phlegmasia of the lymphatics applies not to the other inflammations.

Fifteen times in twenty I have observed the obstruction of lymphatic ganglions preceded by inflammation or suppuration in some other point; the glands of the neck in the scrofulous, for example, are the consequence of former maladies of the head or the mouth; those of the arm-pit relate to similar wounds of the hand, arm, or chest; those of the groin, to an affection of the lower members, or to the sexual organs.

One consequence may be deduced for practice, namely, that with children, among others, it is important that all suppuration should be dried up, all inflammation of the head subdued, instead of the practice which is so often adopted, when menaced with scrofula.

DEVONPORT AND STONEHOUSE DISPENSARY.

At a meeting of the Governors of this Institution, on Saturday, the recommendation of the Committee not to fill up Mr. Watson's vacancy, and to reduce the surgeons to the original number of six, was unanimously adopted.

SINGULAR CASE OF POISONING BY A SPIDER.

ON Tuesday, Feb. 3rd, John Bogle, Old Harbour, and Port Royal, pilot and fisherman, went to Salt River for the purpose of fishing. Having drawn the nets on shore, and feeling himself fatigued, he laid down on the beach to sleep, having previously taken off his wet trousers. On waking about 3 P.M., he felt a particular itching under the pit of the right arm, and on examination found that he had been bitten by a sea spider, probably of the tarantula species. On scratching the place rather violently to appease the irritation he appeared to communicate it to the whole of his body, and, as he himself describes it, directly he rubbed the place, it shot over him, and his extremities were completely benumbed. Shortly after the right side, where the bite had been inflicted, became paralysed, and feeling himself increasingly unwell, he desired his men immediately to row him home to Old Harbour. He reached there about 7 o'clock P.M., and by this time the pain had increased greatly, and the whole of his animal system appeared impregnated with the poison; and at eight o'clock, when the writer saw him, he was foaming at the mouth, and his eyes were rolling wildly from side to side. There appeared to be a strong determination of blood to the head, and he was talking in a very unconnected manner. Some coloured people, two of whom had been previously bitten, and who understood the nature of the disease, had administered a dose of castor-oil, and were rubbing him with an embrocation composed of bruised ginger, pepper, and cinnamon steeped in brandy, to excite a counter irritation. This appeared to compose him, and, the paroxysms being less violent, he appeared disposed to sleep.

11 P.M. pains had returned with increased violence; the extremities were quite benumbed, accompanied with general rigidity of the muscular system; cold sweats stood thickly on him, which required continual wiping off; insensible to every thing around him, except at distant intervals; complained much of burning pain in the head, and shooting pains throughout the body.

At midnight medical aid was procured, and he was bled; the blood was in a bad state, and flowed but slowly; a strong dose of calomel and jalap was administered, which, in the course of an hour, operated powerfully. Hot bricks and bottles of heated water were applied to the stomach and feet, accompanied with general rubbing. This had a salutary tendency, and life began to appear at the extremities.

Wednesday, 6 A.M. Considerably relieved; was able to account for the circumstance, and knew those around him; the right side still benumbed, and the feet cold. Was put into a warm-bath, and as the morning advanced

drowsiness came on, from which he awoke about noon, much refreshed. Throughout the afterpart of the day he continued to mend, and he is now in a fair way of recovery.—*Jamaica (Kingston) Chronicle.*

THE MEDICAL LIBRARY, LIVERPOOL.

THE medical gentlemen of Liverpool have been for some time endeavouring to provide themselves with a suitable building for the reception of their library, with an intended pathological museum and accommodation for the meeting of the profession and the Medical Society. In furtherance of this object, the following appeal is made to the public, from whom pecuniary assistance is solicited, to enable the projectors to carry their plan into effect:

“The medical profession, feeling most anxious that their intentions in erecting a building for professional purposes should not be misconceived, either by the public or any member of their own body, beg respectfully to state, that their only object is to provide themselves with a suitable and permanent building for the reception of their extensive and valuable library, for a pathological museum, and accommodation for the meetings of the profession and the Medical Society.

“The Common Council having most liberally presented the profession with a piece of ground in Duke-street, well adapted to their purpose, and they having raised a considerable sum amongst themselves, are anxious that the present favourable opportunity of carrying their wishes into effect should not be permitted to be lost.

“They regret, however, that they cannot by themselves alone erect a building to the extent that would be desirable or necessary, without greater pecuniary sacrifices, individually, than they would be justified in making, and are therefore under the necessity of appealing to the liberality of the community, to enable them to do so in a manner satisfactory to themselves, and creditable to the town.

“The advantages which must arise from the extended means which will be thus afforded of obtaining professional information, and of the facilities which will be thus given to the meetings of the Medical Society, where the experience of the senior members is so readily communicated to the junior, in all matters of difficulty or doubt—advantages which must necessarily extend their influence to the public generally, are too obvious to require to be dwelt upon.

“They therefore venture to hope, that the appeal, in so laudable an undertaking, of a profession which has ever shown itself ready to encounter all hazards, at the call of humanity and public duty, and whose long, zealous, and gratuitous services in all the public charities of the town give it so strong a claim to the assistance of a wealthy and liberal community, will not be made in vain.”

April 3rd, 1835.

Electricity.

PROFESSOR RITCHIE delivered a lecture on the various theories which have been advanced in reference to electricity. He explained the opinions of Franklin, who considered that a body was positively electrified when it possessed a plus quantity of the electrifying fluid, and that it was negatively affected, when it had only a minus proportion. This theory he showed to be incompatible with the results of certain experiments which have been made since Franklin's time, and he gave his support to the doctrine which considers electricity as consisting of two fluids, which, by certain processes, can be separated from each other. The lecturer then proceeded to make some remarks on the electrophorus, the Galvanometer and on Voltaic electricity, and finally concluded by drawing the electric spark from the magnet. In further confirmation of the observation of Dr. Faraday on a previous evening, he remarked that if a long coil of wire be wound round the magnet, a powerful shock would be obtained, but no spark; if a short coil be employed a spark could be procured, but there would not be any shock. There was little novelty in any part of the lecture.

The Professor, we regret to state, spoke in a very low voice, and was at times almost inaudible where we sat, an inconvenience which was greatly increased by the constant opening and shutting of the doors of the theatre, even long after the lecturer had commenced.

ROYAL COLLEGE OF PHYSICIANS.

Monday March 30th, 1835.

DR. TURNER in the Chair,

The paper first read was written by Dr. Watson, of the Middlesex Hospital, and forwarded through Dr. Hawkins: it was entitled “Observations upon the Connexion of Hypertrophy of the Heart with Cerebral and Pulmonary Hæmorrhage.” Our readers will recollect that at a previous meeting at the College a paper by Dr. Hope was read, in which that physician essayed to prove that hypertrophy of the heart and apoplexy were not unfrequently conjoined as cause and effect. Dr. Watson does not deny that such may be the case in some instances, but he is further of opinion, that cerebral hæmorrhage and hypertrophy of the left ventricle may co-exist as the effects of another disease, to wit, of the aorta and larger arteries. As man advances in years, and in earlier life in the spirit drinker, albuminous and ossific deposits take place in the coats of the arteries indicating a diseased condition of these vessels, rendering their calibre of less size, and their bore unequal,

and to this cause the Doctor is inclined to attribute the cardiac and the concomitant cerebral disease.

The essayist extended his researches to another subject, connected with, but not wholly dependent on, the preceding, namely, the disease called by Laennec and others pulmonary apoplexy. Dr. Watson objects to the term apoplexy as applied to hæmorrhage in the lungs, as tending to cause an assimilation in idea with cerebral hæmorrhage, and he draws a wide distinction between the two, the latter being caused by the rupture of a blood-vessel, the former by exhalation from the mucous membranes, the blood being forced by the efforts at respiration into the lobules. He also differs from most writers as to the cause he assigns for its production. Those who have assumed that hypertrophy of the left ventricle will induce cerebral apoplexy, by giving an undue impetus to the blood in its passage to the brain, have, reasoning by analogy, taken it for granted, that pulmonary apoplexy must be caused by a similar hypertrophy of the right ventricle, but Dr. W. is inclined to attribute its occurrence to a contraction of the left auriculo-ventricular aperture, or to an obstacle at the mouth of the aorta, thus mechanically impeding the return of the blood from the lungs. Dr. Watson's data are founded principally on pathological investigations.

A paper by Mr. Mayo, of the Middlesex Hospital, followed, headed "On the Cause of some of the Symptoms which attend Diseases and Injuries of the Brain." Mr. Mayo commenced his paper with a summary of the cerebral physiology, and, in applying it to the examination of disease, put five questions, which with the answers contain the pith of his essay.

1st. In what manner, or through what kind of influence, does a lesion of the brain produce palsy and numbness? Mr. Mayo rejects the belief that palsy is to be attributed to a withdrawal of the nervous fluid from the part paralysed in consequence of the lesion of the brain, and considers that it is caused by a new and withering influence transmitted from the diseased part of the cerebral mass to the origins of the nerves.

2nd. How does it happen that a lesion of one side of the brain invariably produces palsy of the opposite side of the body? The essayist answered this question by attributing it to a decussation of the fibres of the anterior pyramids in the medulla oblongata. He assumes as a fact that the paralytic seizure invariably affects the side opposite to that where the cerebral lesion occurs,—a statement which the records of pathology do not allow, inasmuch as several cases have been published, and by talented practitioners, where the paralysis affected the same side with the diseased cerebral structure.

3rd. What reason can be assigned for the facts that in total hemiplegia from cerebral lesion, the palsy of the leg is less complete,

and capable of being more quickly recovered from, than palsy of the arm? The explanation Mr. Mayo offered on this subject was in illustration of his doctrine of a withering influence, he considering it feasible and correct that the part first reached by the influence should be more severely affected than the lower extremities, and slower in recovering from the shock.

4th. Why, in a slow attack of palsy, are the muscular weakness and the numbness first felt in the extremity of the affected limb? Why in the hand before the fore arm—in the fore arm before the upper arm? This is accounted for by Mr. Mayo according to the received opinions of physiologists, namely, that is owing to a diminution of the nervous fluid or stimulus sent to the limb, and which, therefore, although sufficient to set the upper part of the limb in action, is not capable of affecting the lower part.

The fifth and last question put by the author of this paper was as follows:—

How is it to be accounted for that muscular palsy is more frequent than anaesthesia? The answer is simple: the sentient nerves require a stronger influence to paralyse than do the motor, and at the same time recover more speedily from its action. Mr. Mayo further remarked, that as the office of the sentient nerve was to transmit its impressions to the brain, and not to receive them from it, it would be much less susceptible to be affected by any influence proceeding from it.

The paper concluded with some remarks on the medulla oblongata, in which, or, rather, in that part where the fifth, seventh, and eighth nerves arise, Mr. Mayo considers the vital powers to reside; at least an injury inflicted upon it instantaneously destroys life.

In the course of the evening, Dr. Tattersall presented to the College Mr. Curtis's map and chart of the ear, being, as far as we were able to learn, the only present of the evening.

LONDON MEDICAL SOCIETY.

Monday, April 6th, 1835.

DR. WHITING, President, in the Chair.

Ovarian Dropsy.

The discussion this evening involved the question of the propriety of injecting the cyst in ovarian dropsy, with the view of effecting adhesion between its parietes. A case had been narrated on the previous evening where this plan had been had recourse to, but unsuccessfully, the failure being attributed by the operator to the long continuance of the disease, and the exhausted condition of the sufferer. The plan was recommended on the grounds of a supposed analogy with hydrocele, the speaker not reflecting that in the latter complaint the fluid is contained in a distinct sac, separate from the organ, and not

of anything like the extent of the cyst in hydrops ovarii; in this latter case, the fluid is contained in the organ itself, a body also which differs very much in structure from the testis, and there is consequently no analogy; besides that, the locality of the two is so very different, that it must, even at a *primâ facie* view of the case, mark a great variance as to the degree of danger each case would be attended with. The proposition was met by the following reasoning:—the principle is that of producing inflammation, and thus causing adhesion of the cystic parietes; the operation of tapping has of itself, without the injection, induced inflammation of the sac, but, instead of curing the patient, has, from the extent of surface affected, gone on to the destruction of life, and consequently any operation tending to produce such a condition of the parts would be indefensible. Moreover, hydrocele is not removed by causing adhesion to take place between the tunica vaginalis and the tunica reflexa, but by arresting the morbid secretion, a plan of treatment which would be inapplicable in the present case. Again it was remarked, that the operation had been occasionally performed, and unsuccessfully.

In the course of the evening some discursive remarks were made upon the nature of inflammation as applicable to pathology, and other means of cure in hydrops ovarii were also alluded to. A case was partly narrated, in which the cyst had been tapped, and, by well-regulated pressure, applied by means of a bandage, a recurrence of the dropsy prevented. Allusion was made to the efficacy of iodine.

Ere the meeting adjourned, a recommendation was hazarded to extirpate the cyst, on the grounds that the lower animals were frequently spayed without any injurious consequences resulting. It was argued, that early in the disease the tumour had not contracted adhesions to the neighbouring parts, and may thus be successfully removed; but it must be recollected, that when the cyst is small, and scarcely attended with inconvenience, in which condition it may remain for years, no surgeon would be warranted in recommending an operation, nor would any patient submit to its infliction. And at a later period, when the disease adheres to the vicinal viscera, and to the abdominal parietes, no one, we think, now, after the well-known Edinburgh operation, would dare to propose it. The recommendation must therefore be—*vox et præterea nihil*.

DEATH OF SIR GEORGE TUTHILL.

It is with regret we announce the death of Sir George Leman Tuthill, which took place on the 7th inst. at his house in Cavendish-square. We understand that his demise was caused by inflammation of the Pharynx. ...

PLAGUE IN EGYPT.

ALEXANDRIA, 19th Feb.—The plague is unhappily spreading, and the number of the victims is daily greater. The government, with laudable zeal, is strictly enforcing its extraordinary measures of precaution. It may, however, be predicted with tolerable certainty that this dreadful contagion will spread still more in the course of the next month. In Cairo there have been hitherto only a few cases of plague; it is said that it has broken out in Upper Egypt also. There has not been for a long time since any case of plague on board the fleet, because it was at once put under quarantine. In a few days it will sail to Suda, there to remain till the plague shall have wholly ceased here.

[Although it is assumed in the above paragraph that the plague is contagious, our opinion on that subject is too well known to require the refutation of such an assumption.—ED.]

EFFECTS FROM CIGAR SMOKING.

MR. CURTIS, in his work on the Eye, relates the following curious case, attributed to this universal practice:—"Lieut. —, a young officer of dragoons, applied to me in consequence of a decided amaurotic affection. His sight was so imperfect, that he could not perceive small objects, even when near to him. He informed me that he had been in this state nearly three months, and that he was daily getting worse. The disease was attended with great debility and emaciation. He was, he said, unable to account for its origin; but, on further inquiry, I observed that he was in the habit of smoking cigars and tobacco to such an excess, that he had brought on a spitting almost amounting to ptyalism. He was what is called an *amateur*; and, to support his pretensions to this enviable distinction, used frequently to begin smoking soon after breakfast, and continue this pernicious custom during half the day without intermission. After this, with much persuasion, I prevailed upon him to leave off this silly modern *accomplishment*, though I had great difficulty in persuading him that this was the true cause of the disease. He however did abandon it; and by so doing, and taking a little tonic medicine, his sight was perfectly restored, and his health regained."

APOTHECARIES' HALL.

It is rumoured that Mr. Warburton's forthcoming Bill for the Regulation of Apothecaries enacts, that they shall not be allowed to compound medicines, but, being regarded as minor physicians, shall charge 10s. for each visit, or 5s. if so agreed. Chemists, alone, to be allowed to compound prescriptions, but to undergo, in the first instance, an examination with respect to their competence.

THE

London Medical and Surgical Journal.

Saturday, April 11, 1835.

THE LONDON UNIVERSITY AND ITS
PROSPECT OF A CHARTER.

WE had intended in our last number to make a few observations on the prospect which the new London University had before it of obtaining the charter for which it has so long contended, and only delayed noticing it then in the hope that we might be able, by waiting a little, to communicate something more decisive and satisfactory to our readers than it is our lot now to be able to do. We believe we need not remind our readers that our principles are adverse to monopoly in whatever shape it may appear, and friendly to all that can advance science, more particularly medical science. With these feelings we had hoped that the granting a charter, at the same time useful to the community and advantageous to this University, would ere this have been a matter of certainty. As, however, the state of its expectations do not now seem very bright, and the cold answer which the King has been pleased to return to the address, from a House of Commons which voted it with a majority of above 100, does not warrant any very sanguine hopes that, under the present Ministry, an appropriate charter will be conferred,—we proceed to say a few words on the subject.

After a hard and dubious battle, then, it appears that the New London University is *still* in doubt whether it shall obtain, at least for some time to come, a charter of even a modified description,—one empowering it to grant academic honours and the initiative degrees of “A. B.” and

“A. M.” Now, as these would confer no peculiar privileges, and only exhibit that a certain curriculum of education had been accomplished by the bearer, and with certain degrees of success, there could be no sufficient objection, we conceive, to this University possessing the power to grant them. It does not ask to confer degrees in divinity, law, or physic, and so far has consulted common sense and the public good,—common sense inasmuch as it would not be wise to permit the preceptor to be the final judge of his pupil’s acquirements; public good, because an odious monopoly would be avoided.

Had the tenor of the charter prayed for gone so far as to authorise giving degrees in divinity, law, and physic, there can be no doubt that the address, now so unsatisfactorily answered by the King, would not have been voted, as Mr. Warburton and a strong party in the House were opposed to such an extent of privilege, upon the ground that so much power concentrated in one focus would have attracted within its circle an undue share of patronage, and militated against the interests of other, and quite as effective, schools in the metropolis. Had such power been sought, a strong opposition would have been excited, and the eventful history of the charter in 1831 been in all probability repeated. That there has been no occasion for such a course in the present instance, and that moderate views have taken the place of more grasping and more ambitious ones, we think a subject for congratulation; as we believe there is ample room in this enlightened and populous country, not only for the London but half a dozen similar Universities. Taking this view of the matter we should say, whenever the desired charter is bestowed upon the College in Gower-street it should not be exclusively

conceded to it, but a similar one granted to King's College, and if perchance a third establishment should arise in the eastern districts of London, *that* likewise should be endowed with like privileges.

The times are now gone, we trust, when degrees in arts, and the advantages of academic honours, are to be enjoyed by an exclusive few, viz. the members of the Church of England at the Universities of Oxford and Cambridge. Toleration, which has marched on with a steady step in all else, has paused here. The moment is arrived when it must tread on the obstacles which have hitherto impeded its onward course. The portals of other sources of doctrinal honours must be opened wide, since the sister Universities have willed their narrow wicket impassable to any but one sect.

The mode in which the Universities in question, when chartered, may become highly beneficial to the medical profession is this:—The College of Physicians demands, under its existing regulations, a certain period of residence at a University prior to allowing an examination for their licence, and this residence may be at any recognised University, either at home or foreign. As there is no University recognised as such at the present period in London, the penalty—often a grievous one—of going at a great expense to Oxford, Cambridge, or other distant parts, possessing such seats of education, is imposed on all who intend entering this College. Under the new aspect this desideratum would be supplied, as it ought to have been long ago at the metropolitan head; and, since it is all but certain that the new laws to regulate the medical profession will only require a degree in arts, together with a sufficient curriculum of professional study obtained at *any* school in order to be eligible for examination,

the aspirant for a medical degree may fulfil his intentions without quitting the metropolis. How far it might be advisable that the new University or Universities should be compellable to examine for, and confer their degrees upon, such as have not studied at them might be a question; for it is well known that there are many fully capable and desirous of undergoing the necessary examinations, and to whom the clog of a two or three additional years' attendance, and learning over again what they are already masters of, would be intolerably burthensome, both as regards time and expense. The most liberal policy would appear to be, that the new establishment, having the power of granting the before-mentioned degrees, should do so in every instance where the candidate is able to pass the required examination, without reference to the place or mode of obtaining his knowledge,—solely on the basis of merit and acquirements.

We are aware that some jealousy about the term of Bachelor or Master of Arts has been exhibited in certain quarters, upon the ground that some confusion might ensue, and those long-monopolised titles become depreciated in consequence of the uncertainty of the public as to the source whence they were derived; but if the quantum of education necessary to obtain these degrees be regulated in the new Universities by the standard of those of Oxford and Cambridge, the objection, such as it is, falls to the ground, since the amount of knowledge ought to be alone the just criterion. The antiquated step-dames of science then could not be disparaged by the assumption of the same names for the same things. Of one thing they may feel assured, that, ratiocinate and oppose as they please, to such a complexion affairs will come at last.

As the charter will not empower the new University to grant diplomas or licences to practise medicine, we believe it is intended to form a distinct board, competent to examine in all branches of science requisite for obtaining them. This will render the pupil far more independent of his teachers than he now is. The mode in which the members of this board are to be selected has not transpired, but at all events, when constituted, it will be a remedy for many existing abuses in the examining department.

In fine, we could wish that the University, which we have no doubt will soon obtain a charter, had shown itself a little more forward as a scientific institution. Hitherto its march has been awfully slow; and, although it has possessed and possesses many eminent professors in the various walks of science, their efforts have not been able to raise it into any great degree of note: obscurity clings to it. There is space enough and ample building, and we earnestly hope that its future progress may vindicate to itself a brighter fame.

BREACH OF CONFIDENCE IN A PHYSICIAN—CRIM. CON. OF A PHYSICIAN WITH HIS PATIENT.

ALTHOUGH no admirers of hanging out, for the scrutiny of the public or our readers, the failings or even delinquencies of such of our profession as step aside from the path of rectitude and honour, we find ourselves constrained this week to notice a breach of confidence committed by one practising in the highest branch of medicine. The party in question, Dr. Webster, of Shrewsbury, has thought proper, instead of exhibiting to his subordinate brethren a high moral example, to violate that confidence which should ever subsist between the patient

and medical attendant. The case against Dr. W., we are happy to say, is one of no common occurrence in the medical world, and involves more than ordinary culpability,—it is the seduction of his patient, the wife of one who placed in him unbounded trust. The facts are,—the plaintiff, Mr. Wilton, is a respectable mercer and draper carrying on business in the town of Shrewsbury; having formed an attachment to Miss Eliza Hughes, then twenty years of age, he was married to her in 1825, being then himself twenty-nine years old. She was a young lady of personal attractions and some accomplishments. They had three children, one of whom only survives. For several years the plaintiff and his wife lived in happiness together, until they became acquainted with the defendant, who is a physician residing in Shrewsbury, where he has practised during the last nine years. Having been called in to see one of the plaintiff's children in the year 1833, Mrs. Wilton also became his patient. Dr. W. recommended the husband to remove her into the country for the benefit of her health, which was done, and the Doctor still continued to visit her. The plaintiff himself became unwell, and was recommended by the defendant to go on a *tour to the Highlands of Scotland*; and it was during this absence of the confiding husband that it is supposed Dr. W. succeeded in corrupting and obtaining possession of plaintiff's wife. When the latter returned he was received with apparent affection; and Dr. W., wishing to link himself more closely with his victim, proposed taking lodgings in plaintiff's house. Some reports, however, had gone abroad relative to his conduct; but, to disarm all suspicions, Dr. W. went himself to the plaintiff and stated them, denying their truth. Subsequently he lodged

and boarded in the same house with his victim and her husband, thus enjoying ample opportunity to pursue the career he had begun. Mrs. Wilton fell into a confirmed state of illness; she had no organic disease, but was in a state of great debility, and soon after died. Whether the sense of her guilt, and anguish of mind contributed to bring her to her grave, cannot now be known, but for fourteen months, from August, 1833, to last December, she lingered in this state. Her husband attended her with affection and care. On the 4th December her brother came to see her, and on the morning of the 5th she disclosed her guilt to her husband, who had been lying at her bedside during the night,—her brother was also present during this disclosure. Dr. Webster was sent for and came. Mrs. Wilton addressed him, her words were “Dr. Webster, I have told George that the reports against us were true.” The Doctor answered, “Mrs. Wilton, I will make you any sacrifice,” and quitted the room. Soon after she died. The evidence on this trial fully bore out the case, and the Jury awarded 500*l.* damages against the performer of this anti-professional piece of duplicity. We have laid these facts before our readers because we consider that the respectability and the moral character of the profession are injured materially by such conduct, on the part of one of its members, and that the castigation of publicity should, in such cases, ever accompany the award of pecuniary damages, however great.

COLLEGE OF PHYSICIANS.

THE papers, read at the College of Physicians at the last meeting, were *two*,—one short paper on apoplexy by Dr. Watson, and another by Mr. Mayo “On

the Origin of Palsy as a Consequence of Disease or Lesion of the Brain.” The author adduced arguments to show that palsy occurred not from an interruption of the ordinary supply of nervous energy, but from a depressing influence communicated by the diseased brain to the nerves. He inducted from this, that palsy is not to be always treated by depletion, it being a disease of depression. Now and then instances might arise indicating depletion, but the palsy would not be directly benefited thereby, and if this plan was injudiciously used it might prove fatal. The meeting was very fully attended.

British Hospital Reports.

GUY'S HOSPITAL.

Ossification and Ulceration of the Cartilages of the Larynx, with Fistulous Opening.—George Blackgrove, æt. 48. During the former part of his life he was employed in some iron-mills, and was accustomed to drink spirits freely; but his habits lately have been temperate. He received a severe burn on the head five years ago, which healed very slowly (in 12 months), and reduced him considerably. After that, his occupation was changed, and he worked in a tan-yard, where he was much exposed to damp and cold: the early consequence was an abscess, which formed behind the left ear, and proved as troublesome as the burn. After having been a patient at several public institutions, he was at length cured in 15 months. For the last four or five weeks his health has not been so good as usual; and fourteen days ago he had a small swelling, attended with pain, on the left side of the larynx, followed successively by two on the opposite side: they all burst, and discharged much. Four days before his admission he noticed a hissing sound proceeding from the ulcer on the left side, and he coughed almost incessantly for about two days; at last he applied for relief at the hospital as an out-patient. He was admitted to the house the following day, Jan. 3rd; and, on examination, a large portion of the cricoid cartilage on the left side, and of the thyroid on the right, was found ossified and denuded. There was a fistulous opening through the crico-thyroid membrane, through which air passed very freely while speaking, and generally without giving pain. He states, that six months ago he strained himself while carrying a heavy weight, and that his throat has always been uneasy since.

Local applications, and those of a very mild nature only, were applied for several days. On the 7th January Mr. Key ordered him—

Iodinæ, gr. ss.; potass. hydriod., gr. iij.; syrup. papav., ʒss.

10th. His appetite, which was deficient when he was admitted, is increased; the ulcers somewhat improved, appearing less inclined to extend.—Pergat.

12th. Mr. Key attempted to remove a portion of the cricoid cartilage, but found it firm.

16th. His health and appearance are both much better; he requested a more plentiful diet, which was allowed him. A small portion of the cricoid cartilage was removed.

20th. He was ordered, as a gentle stimulant, a lotion of very dilute nitric acid (gtt. ij. ad ʒj. aq.); but, by mistake, he applied some pure acid, which was in the ward. This destroyed the integuments to some extent, but does not appear to have affected the cartilage.

21st. The ulcer is much inflamed. No ill effects followed the application of the acid, except the extension of the ulcerating surface. Bread poultices were applied, and the iodine continued.

23rd. His throat is much better; the cartilage appears quite firm, and the ulcers on the right side cicatrising.

28th. The smaller ulcer on the right side healed. One bare spot of cartilage can be felt by the probe, in the larger one on the same side. The opening in the larynx on the left side smaller.—Pergat.

The opening was closed on the 12th Feb. and he left the hospital quite well about three weeks afterwards. He suffered no inconvenience from the iodine.

WESTMINSTER HOSPITAL.

External Application of the Iodine.

CASE I.—*Inflamed Bursa on the Knee.*—Elizabeth Vanderbrost, ætat. 26, a servant, was admitted into Anne's Ward, October 15th, 1833, under Mr. Guthrie. Is a servant, employed in the kitchen, but not as housemaid; says she has not been accustomed to do work on her knees, but latterly has been so engaged. Complains of stiffness of the right knee, and considerable pain, with difficulty of walking; on examination an elastic tumour on the anterior aspect of the joint, a little above the insertion of the ligamentum patellæ, presented itself; it was of an oval shape, and showed evident fluctuation; the integuments were undischoloured, nor was there any external inflammation apparent; health unaffected.—Ordered to remain quiet in bed, and have the tinct. iodinæ applied.

17th. The disease is much the same as at last report; complains of the pain caused by the application of the iodine; ordered to have it repeated daily, and a poultice at night.

19th. The tumour is lessened in size, and she says that when the pain from the iodine has ceased, she finds that that which she had previously experienced in the knee is materially lessened.

23rd. The original pain has entirely disappeared, and the bursa is not one-half the size it was. The iodine is now to be applied twice a day.

Nov. 9th. The knee has gradually but slowly improved since the last report, but it now appears to be stationary; her chief complaint is weakness in the joint. Ordered the ung. hydrarg. fort. c. camphorâ spread on lint to be applied over the whole knee, and secured by strapping, encasing the joint with pasteboard splints on each side of the joint, and in the ham, made to adapt themselves to the shape of the parts by being previously soaked in warm water, and kept *in situ* by a bandage. By these means the joint was kept immoveable.

This apparatus was kept on for a week, and then removed, no other advantage being derived from its use than might be obtained by keeping the limb steady. The pasteboard splints and roller only were re-applied.

She was dismissed on the 7th of December, cured.

During the past year, many cases of enlarged bursæ have been admitted into the hospital, and treated by the external application of the tincture of iodine, and with success. The iodine used in this manner proves a powerful stimulant and rubefacient, and, in some cases, a vesicatory. It should be applied with a feather every day, until the skin assumes a deep-red colour; a poultice at night will remove the epidermis, and the next day the iodine should be re-applied.

CASE II.—*Syphilitic Enlargement of the Tibia.*—Elizabeth Bonney, ætat. 33, residing in Smith's Rents, was admitted into Anne's Ward, September 24th, 1833, under Mr. White. Atrabilious temperament; tall, thin, and rather pale; has been married ten years, but has not had any children; had one miscarriage; three years and a half ago her husband gave her the venereal disease, does not know what symptoms he had; did not have either sores or buboes herself, nor has she had any inflammation of the eyes or sore throat; has had leucorrhœa for the last fourteen months. She has had a venereal, copper-coloured eruption on her skin, according to her own account, which appeared over the whole body, and continued on her a month; she took sulphur and the super-tartrate of potass in treacle for it, and applied simple ointment on the spots. Within the last twelvemonths, pains in the shin-bones and arms, increased in severity at night time, have come on, and are very severe; has had her mouth made tender, but, when it had proceeded so far, she left off the mercury, never

carrying its effects to actual salivation. For the last year, she has been very irregular, scarcely seeing any thing, and sometimes missing whole periods. Has been an out-patient of the physicians of the hospital for some time past; under the treatment then adopted she improved so much that she gave up her letter; the disease has since suffered a relapse.

The left shin-bone, about its centre, is considerably enlarged and irregular, or rather the enlargement gradually rises from the upper part of the tibia to the centre, where it is the greatest, and then as gradually diminishes; the pain she suffers at night she describes as being so great as in a great measure to prevent her sleeping.

R. Decoct. sarsæ. Oj.,
Hydrarg. oxy-mur. gr. $\frac{1}{4}$.—Solve.
Capiat dimidium bis in die.

The tincture of iodine to be applied externally over the enlarged tibia.

28th. Has had an occasional anodyne, by which she rests better than she did. Mr. White saw her to-day, and desired the oxymuriate to be omitted, as he was anxious to try the effect of the iodine on the diseased bone without mercury.—To continue the sarsaparilla.

Oct. 1st. Has hitherto had only one anodyne, and she says the pain in the limb is much diminished.

3rd. The iodine has caused great pain and vesications; ordered to be omitted.

5th. The iodine is again applied; thinks the irregularity of the bone is lessened.

10th. Has had some slight irritation of the system, with sore-throat and headach, for which she was ordered cathartic pills and diaphoretic mixture; she is now much improved.

13th. The febrile excitement has nearly subsided, but the irregularity of the tibia appears to be greater.—Reapply the iodine.

22nd. The enlargement is evidently lessened. She was made an out-patient, and directed to attend every other day, which she neglected to do, coming only occasionally, consequently the enlargement increased.

CASE III.—*Enlargement of the Leg, resembling Elephantiasis.*—Elizabeth Cross, æt. 24, was admitted July 30th, 1833, under Mr. White, into Anne's Ward. Is a short, stout woman, sanguineous temperament, of very irregular habits. The right leg has been enlarged to a greater or less extent for the last three years; has been in this hospital twice before for the same complaint, and has hitherto received but little benefit; the whole of the leg and foot, stopping just below the knee, are equally enlarged to rather more than double their natural size; the whole of the limb firmer and harder than usual, the integuments undiscoloured, and apparently clear from any disease. The sudden arrest of

the enlargement just below the knee is sufficiently remarkable; the little toe of that foot has been ulcerated for several months, and, although it appears to have healed, it is still exceedingly painful; the tumefied leg pits upon pressure, the pit remaining for some time after. It does not give her any pain, but she finds it a great inconvenience. The left leg is sound.

She attributes the supervention of this disease to erysipelas; previous to the first attack (and she has had three), the leg was of the same size and shape as the other, and the limb gradually enlarged after each.

Sept. 17th. Several remedies have been tried to reduce the size of the limb, but hitherto ineffectually, more particularly the pustulation by the ung. ant. tart. and bandaging. Mr. White to-day ordered pressure to be excited by the medium of Mr. Younge's plaster, spread on calico, then cut into slips, and applied equally over the limb.

R. Emp. saponis, emp. thuris, partes equales, resinæ flavæ paucillum.—
M. fiat emplastrum.

18th. Complains that the bandage is too tight, and that it has induced great pain.—Let it be loosened.

21st. The whole of the plaster removed, and the leg found to be in a state of severe inflammation; not to be reapplied. Mr. W. ordered her to use exercise, but afterwards directed the external application of the tincture of iodine, with a feather, over the limb.

Oct. 3rd. The iodine is so freely applied as to give a deep colour to the limb; it appears to have reduced the limb somewhat in size; she is sick, and complains of headach, with constipated bowels.—To give up iodine for the present, and take aperient medicine.

12th. Let the iodine be reapplied.

Nov. 2nd. Is much improved; the limb is certainly smaller and softer; let the iodine be reapplied daily.

Dec. 3rd. The limb is now about a third smaller than when she commenced with the iodine; it has been applied almost daily since the last report, but so slightly at times as to produce but little effect. She has remained in the hospital considerably beyond the time patients are allowed to stay in by the laws of the institution (to wit, two months), and is now dismissed.

This patient was readmitted into the hospital soon after the new establishment was opened; the disease was then as bad as ever; it was treated by punctures, and after a certain time an incision was made into it. Some benefit was derived, but she again left the hospital ere a complete cure could be (if it were possible) effected, and her complaint returned afterwards to its full extent. She is of very intemperate habits.

CASE IV.—*Anomalous subcutaneous Tumour—Varicose Veins.*—Charlotte Vincent,

æ. 27, tall and thin, of the nervo-sanguineous temperament, with features approximating to those of the gipsy-tribe, was admitted under Mr. Guthrie, June 11th, 1833. Is not married, nor has she borne children. Came in for a tumour situated on the inside of the left leg, just below the knee, smooth and flat, about the size of the palm of the hand; oval in shape; moveable in every direction except at the upper and inner part, where it appears to dip down into the ham, and to be there lost. The tumour is very firm, having few depressions on its surface; the skin covering it is of a darker hue than elsewhere. She considers that this tumour has not existed more than a week, although she can call to mind that a small knot, as she terms it, has been in that situation for years. The saphena vein can be traced up the inside of the leg, completely varicose; it appears to anastomose very freely, in a congeries of veins in a similar condition, over the surface of the tumour, and to pass a little way up the thigh in the same unhealthy state; the skin over the vein is discoloured. This varicose condition of the vein has existed some time in the left leg; the right is unaffected. She complains of sharp darting pain in the tumour; her health is out of order. The disease was at first mistaken for an abscess, and poulticed accordingly.

21st. Mr. Guthrie saw her, and ordered the surface of the tumour to be well blistered by the external application of the tincture of iodine, with a poultice at night to detach the epidermis.

It was applied two or three times in the course of the day, and by the next the skin had assumed a dark-red colour, and was covered with small vesications; the application did not cause much pain. By the 25th considerable vesication had formed, and the use of the iodine was accordingly intermitted; the tumour appeared to be rather smaller, and the varicose veins were less apparent. By the end of the month, the enlargement of the veins had entirely disappeared, and the tumour was lessened in size, and not so much elevated above the surrounding parts. She had, in the interim, suffered from an attack of corneitis in the left eye, caused by her applying her finger to the eye when it was wet with the tincture of iodine. This was soon cured by the stimulant treatment. In the course of the next month, considerable diminution took place, but in August little progress was made. She began to get tired of the tincture, and did not apply it with the same care as heretofore; the disease, however, yielded to the treatment which has been detailed, and, on the 3rd of September, she left the hospital freed from all vestiges of her tumour and varicose veins.

CASE V. — *Hydrocele — Considerable Chronic Tumefaction after the Operation — Use of Iodine.*—James Knight, ætat. 55, a countryman, from Curricots, Herts, was ad-

mitted under Mr. Guthrie, March 19, 1833, into John's Ward. Is a tall, stout, hale-looking man, of a very powerful build; sanguineous temperament; has no other ailment than extreme deafness, with the exception of that for which he was admitted; has hydrocele in each tunica vaginalis; that of the right side being considerably the larger. The affection commenced about three years ago, the swelling beginning at the bottom of the scrotum, and gradually increasing in size; the right tumour has made rapid progress of late. Poised on the hand, the tumours give the sensation of a very weighty body, are elastic, smooth, and transparent, and so large, that the penis appears buried between them, and the testicles cannot be felt. The length of the right hydrocele was ten inches and four tenths; its circumference, from the raphe anteriorly to the raphe posteriorly, ten inches and nine-tenths; length of the left, six inches and nine-tenths; circumference, seven inches and two-tenths.

Mr. Guthrie, considering the right hydrocele far too large to inject, on account of the immense surface which would inflame, and the dangerous consequences which might ensue, determined to puncture it, and draw off its contents, and when it had acquired a moderate size, to perform the operation for the radical cure. About two pints of a clear, straw-coloured fluid were drawn off, and the patient sent to bed; slight inflammation came on, but was speedily subdued.

On the sixth of April, the tumour on the right side being as large as the left, both were punctured, and five ounces of fluid drawn off from each. Rather a larger quantity of common water was then injected, and kept in while two hundred were counted. He was afterwards sent to bed, and directions given that if pain did not come on, he should be made to walk briskly about until it did. For this there was no occasion; a sharp attack of inflammation ensued, requiring the repeated application of leeches and cold lotions, with purgatives, &c., to subdue it, and leaving behind an enlarged state of the testes themselves apparently.

About the beginning of May he was directed to rub in a drachm of blue ointment daily, to excite absorption, which plan was continued throughout the month, without advantage. In June, therefore, the external application of the tincture of iodine was had recourse to, and applied so freely and so often as to cause considerable inflammation and tumefaction, with burning heat and pain, so much so, that although, when these symptoms were removed, the testes were evidently much lessened, the man dreaded the iodine so much, that he would not consent to its re-application. The blue ointment was therefore continued throughout the month, and he was discharged in July, nearly well.

APOTHECARIES' HALL.

Names of Gentlemen to whom the Court of Examiners granted Certificates of Qualification on Thursday, April 2, 1835:—Alfred Lord, Northiam, Sussex; James Frederick Gilby Wright, London; Nicholas Grant, Leeds; John Watkins, London; Edward Burnham, Grimsby; John Adams Sherwell, Ivy Bridge, Devon.

MISCELLANY OF FACTS.

We understand that Mr. Alexander will not operate on his Royal Highness the Duke of Sussex, but that the eminent surgeon and oculist, Mr. Guthrie, has been engaged for that purpose.

Mr. Osborne, late assistant surgeon to the Thunderer, has returned to this country from the West Indies invalided.

Considerable progress has been made by the Committee appointed to obtain contributions for erecting the "South Devon and West Cornwall Hospital." There have been contributed about 2,500*l.* for this object, and as soon as 1,000*l.* more have been collected the building will be commenced. Amongst the larger benefactions we find Lord Valletort, 200*l.*; Lady Valletort, 50*l.*; Dr. Younge and Mr. Gill, 100*l.* each; Sir J. B. Y. Buller, Bart., M.P., T. Bewes, Esq., M.P., P. Schow, Esq., Mrs. Bint, Mrs. Hodson, R. Bayly, Esq., Earl St. Germain's, Earl Morley, E. P. Bastard, Esq., and the late Mrs. Fox, 50*l.* each.

APPOINTMENTS.

Naval.—Mr. Edward Newman, assistant-surgeon to the Lapwing. Mr. James Taylor, assistant-surgeon to the Tartarus. P. Aldrich, assistant-surgeon, Convict Establishment, Chatham.

Military.—Surgeon John Shutt, M.D., from the 79th Foot, has been appointed surgeon of the 21st regt., vice William Byrnt, who retires upon half-pay. Staff Assistant Surgeon Wm. Dawson, M.D., to be surgeon of the 50th regt., vice Wm. Maikham, who also retires upon half-pay. Assistant-Surgeon John Lorimer, M.D., from the 24th regt., to be surgeon of the 79th Foot, vice Shutt, appointed to the 21st. Assistant-Surgeon John Donald Grant, from the 95th Foot, to be assistant-surgeon of the 82nd Foot, vice Shanks, promoted in the 55th. J. Mellis, M.D., has been appointed assistant-surgeon to the forces, vice Drummond, appointed to the 14th Foot. J. C. Cameron, M.D., also assistant-surgeon to the forces; and Messrs. W. Hamilton and C. Cowen have obtained similar appointments.

General.—Dr. Robert Dyce, physician to Robt. Gordon's Hospital, Aberdeen, in the place of his late father. Dr. Aston and Dr. Ronayne, superintendents of two new dispensaries just opened in Castlebar, Ireland. Mr. Thomas Goyna, of Leicester-square, surgeon to the parish of St. Martin's in the Fields. Mr. T. Sullivan, surgeon, superintendent to the government emigration ship Canton, for New South Wales. Dr. James Clark, physician in ordinary to the Duchess of Kent, in the place of the late Dr. Maton.

Great mortality has taken place on board the convict ship off Woolwich; not less than four inquests have been held in one day this week before C. J. Carttar, Esq., coroner, upon the bodies of convicts who have died on board the *Justitia*. The verdict in each case was that "death ensued from natural causes."—*Kent Herald*.

Phrenological Society.—Dr. Elliotson, F.R.S., in the Chair.—A gentleman, in the absence of any paper being read, got up and expatiated upon the peculiar craniological developments in paupers—not adventitious paupers, but such as are habitually so. He instanced that one gentleman, a friend of his and no mean phrenologist, who had obtained the situation of assistant commissioner of poor laws, had plouted out in many cases the

inclinations of paupers submitted to his inspection, and thence detected their secret habits, and done much good.

Resignations.—Mr. Heath, senior resident-house-surgeon to the Birmingham Dispensary. Dr. Gilliland, superintendent of the Rutland Dispensary, County Donegal.

DEATHS.

Sir George Leman Tuthill, Knt., M.D., of Cavendish-square. At Chester, Mr. Edward Owen Snow, surgeon, formerly of Beaumaris. Mr. A. D. Wilson, surgeon, R.N., at the Royal Naval Hospital, Stonehouse. Mr. Henry Currey Cape, of Low Ireby, Cumberland, surgeon. Mr. Archibald MacRae, surgeon, of Buccleugh-place, Edinburgh. Dr. William Dyce, F.R.S., and physician to Gordon's Hospital, Aberdeen. Dr. W. J. Field, Booterstown, near Dublin, of malignant typhus fever, caught in his attendance on the poor. Mr. Robert Burnett, of Rothbury, surgeon.

Principles of the Treatment of Gout, with a further Examination of the Effects of Colchicum as a Remedy, and some Observations on the Use of Veratrin in that Disease. By SIR CHAS. SCUDAMORE, M.D., F.R.S., &c. Longman. 1835.

The Oration delivered before the Medical Society of London at their sixty-second Anniversary, 1835. By WALTER C. DENDY, M.R.C.S., &c. Clowes.

CORRESPONDENTS.

From our Paris Correspondent.—Typhus fever, which for some time past has been raging in Paris, has within the last week greatly increased. Several cases have been admitted into the *Hôtel Dieu* under M. Chomel. The medical students have not escaped, some have died, and many are lying in a very dangerous state.

Well-Wisher.—His communication shall receive due consideration.

All Communications and Books for Review to be forwarded (free of expense) to the Publisher, 356, Strand, near King's College.

CLINICAL LECTURES

DELIVERED BY

ROBERT J. GRAVES, M. D.,

*At the Meath Hospital during the Session of
1834-5.*

LECTURE VII.

General remarks on the Pathology of Paralysis—Dr. Graves's new views upon this subject—Their application to the study of several varieties of Paraplegia—Explanation of Mr. Stanley's cases of Paraplegia—Of Dr. Stokes's Cases—Two Cases of Paraplegia after Enteritis—Paraplegia after Metritis—Paraplegia the consequence of Poisoning by Lead—By Arsenic—Paraplegia arising from Irritation of the Urethra (Case communicated by Dr. Hutton).

GENTLEMEN,—Having recently met with some very interesting and remarkable cases of impairment of the muscular functions of the lower extremities, I am anxious to offer a few observations on paraplegia, particularly while the subject is still fresh in my mind: we can resume the consideration of our clinical cases at a future opportunity. I would entreat your favourable attention on this occasion, while I lay before you some opinions on paraplegia peculiar to myself, and differing from the views entertained by the generality of medical writers; the subject, too, is one of extreme interest, involved in much obscurity, and offering an extensive field for investigation; I trust, however, I shall be able to communicate some new matter calculated to throw much additional light on the nature of this affection, and thus contribute to fill up the blanks which exist in an important department of pathological medicine.

You are aware that by paraplegia is meant that species of paralysis in which the lower extremities are affected, a paralysis frequently embracing loss of motion and loss of sensation in the lower extremities, accompanied in many instances with derangement of the motor

power of the bladder and rectum. Now I wish you clearly to understand that it is not my intention to describe the symptoms or discuss the causes of those species of paraplegia which are well ascertained, and of which you will find satisfactory descriptions in your books; under this head may be classed all those cases which are produced by disease of the spinal marrow, its membranes, the vertebræ or their appendages, their ligaments, and diseases directly affecting the great nerves which supply the lower extremities. All these matters have been sufficiently studied, and require no additional observations from me; my object is to elucidate some of the obscurer varieties of paraplegia. I have touched on this topic before in my lectures delivered at the Meath Hospital, but since that time I have met with many cases and made inquiries which tend to throw additional light on the subject. I have read with the attention which it merits a lecture on this subject, published by my colleague, Dr. Stokes, in Renshaw's *London Medical and Surgical Journal*, and also Mr. Stanley's interesting cases in the 18th vol. of the *Medico-Chirurgical Transactions*, published in the year 1833. In Mr. Stanley's paper, several cases of paraplegia are brought forward, the explanation of which had not been understood before or even at the time he wrote, but which I had given several months previously, as applied to paralysis in general, in two lectures in the 58th and 59th numbers of the *London Medical and Surgical Journal*, and which had been delivered at the Meath Hospital, in Nov., 1832, and were published immediately afterwards. In fact, the explanation offered by Mr. Stanley is merely a corollary of the propositions which I laid down at that time, and which I shall beg leave to repeat here.

Before I commenced my investigations on the subject, pathologists, in endeavouring to ascertain the causes of paralysis, sought for the sources of the disease almost solely in the centres of the nervous system. They looked for the causes of paralysis in the brain or spinal cord, where they supposed it originated either in organic or functional derangement of these important organs. In the lectures to

which I have already referred, I showed that this mode of accounting for all forms of paralysis, by referring them to original disease of the nervous centres, was in many instances incorrect, and proved, I think to the satisfaction of the class and those who read the lectures, that a most important and influential cause of paralysis had been hitherto nearly overlooked, a cause which, commencing its operation on the extremities, and not on the centres of the nervous system, might, by a reflex action, produce very remarkable effects on distant parts. I brought forward on that occasion many arguments, facts, and cases, to prove the possibility of such an occurrence, to show that it frequently happens that impressions made on the extremities of the nerves will generate a morbid action in them, that this morbid action will be conveyed along their branches and trunks to the spinal cord or brain, and that, continuing its propagation, it may, by a retrograde course, be carried thence along the nerves to distant organs, and in this way give rise to disease in parts originally intact and healthy. I brought forward several instances to prove that when a certain portion of the extreme branches of the nervous tree has suffered an injury, the lesion is not confined merely to the part injured, but in many instances is propagated back towards the nervous centres, and that in this way not only the nervous filaments of the injured part may be affected, but also the main trunk of the nerve and other branches; or that the lesion may reach the brain or spinal cord, and thus produce still more extensive effects on the system. What I endeavoured to impress upon the class at that time was, that pain, numbness, spasm, and loss of the power of muscular motion, may be produced by causes acting on the extremities of the nerves, and that such affections commencing in the extremities of the nerves may be propagated towards their centres so as to be finally confounded with diseases originating in the centres themselves. For a detailed account of my views on this subject I beg leave to refer to the published lectures; at present I shall content myself with recapitulating a few of the facts on which these views were grounded.

If you place your hand in snow or ice-cold water, you will find that it is not merely the parts subjected to the influence of cold that become numb, and that the diminution of power is not entirely limited to the muscles concerned in the peculiar motions of the fingers, but extends also to those of the fore-arm, by which the principal motions of the hand are performed. Here the impression of cold is found to affect not only the parts immediately exposed to it, but also parts that are quite removed from its influence and warmly covered. We see that not only the muscles attached to the fingers, but also those of the fore-arm, undergo from this cause a temporary paralysis. Now, if a

cause of a trifling nature, and acting only for a time, can, when applied to a part, produce loss of power in another and more central part, we may infer that the same cause acting permanently might produce permanent paralysis of the latter. We can therefore conceive how in this case the agency of cold might travel upwards and reach the muscles of the arm also, and thus we should have a change, commencing in the tips of the fingers, propagated to parts at a considerable distance from the situation of the original lesion. Again, we find that an injury affecting one branch of a nerve will be propagated by a retrograde action so as to affect another and distinct branch, as was exemplified in a case mentioned in my former lectures on paralysis. A young lady, having wounded the inside of her ring finger with a blunt needle, observed that she had, in consequence of the injury, a considerable degree of numbness, not only in the wounded finger, but also in the little finger next to it. Here we find that an impression made on the nerve of one finger not only affects that finger, but also travels backwards so as to operate on the branch given off by the ulnar nerve to supply the little finger, and given off, observe, above the place of the wound, so that the phenomena were identical with those which would arise from an injury inflicted on the branch which supplied both fingers. Within this last month, I have had an opportunity of witnessing a very striking fact of this nature. A young gentleman, distinguished for the extent of his classical and mathematical acquirements, and who had just succeeded in obtaining the senior wranglership, swallowed a small but angular piece of chicken-bone. It lodged low down in the œsophagus, and was not pushed, by means of a probang, into the stomach until after the lapse of more than an hour. Considerable inflammation of the pharynx, œsophagus, and surrounding tissues, was the consequence; on the third day of his illness he got a violent, long continued, and ague-like rigor, which terminated in a profuse perspiration, and ushered in a well marked inflammation of the neck of the bladder. In the next place, we find that impressions affecting the frontal branches of the fifth nerve may, by a reflex action, operate on the retina so as to cause blindness. Here the morbid action travels from the circumference towards the centre, and is again reflected towards the circumference so as to affect a separate and distinct part. Of this I lately saw a curious and instructive example. A medical student, travelling through Wales on the outside of the mail, was exposed for many hours to a keen north-easterly wind blowing directly in his face. When he arrived at the end of his journey he found that his vision was impaired, and that every thing seemed as if he was looking through a gauze veil. There was no headache, no symptom of indigestion, to account for this evidently slight degree of amaurosis, and yet he was recommended to use cupping

to the nape of the neck and strong purgatives. When he consulted me, which he did in the course of a few days afterwards, I at once saw that there was something unusual in the case, and, after a careful examination, I at length elicited from him the fact of his having been exposed to the influence of the cold wind. It was now apparent that the retina suffered in consequence of an impression made on the facial branches of the fifth pair. The cure was effected, not by a treatment directed to relieve cerebral congestion, but by stimulation of the skin of the face, forehead, temples, &c.

It is, however, unnecessary to multiply examples to prove the truth of the proposition, that disease may commence in one portion of the nervous extremities, and be propagated towards the centre, and hence, by a reflex action, to other and distant parts. Bearing this in mind, we can explain why it is that disease commencing in one part of the system may produce morbid action in another and distinct part, and it certainly appears strange, that, with so many striking examples before them, pathologists should have so long overlooked this cause, when seeking to explain the nature of many forms of paralysis. If certain irritations of the nervous extremities in one part of the body are capable of giving rise to a derangement in the whole system of voluntary muscles; if a local affection may become the cause of exalting and rendering irregular the functions of every muscle in the body; then, surely, it is not difficult to conceive that a cause, local as the former, and tending not to exalt but to depress the motor function of the muscles, may likewise affect not merely the nerves and muscles of the part, but also those of the whole body or of distant organs, giving rise to paralysis. Now, pathologists have long recognised the fact, that general muscular excitement and spasm may arise from the operation of a local irritation. A man gets a contused wound on his thumb or one of his fingers, and some superficial nerves are injured. In the course of a few days he begins to feel a degree of stiffness about the lower jaw and muscles of the neck, accompanied by a sense of constriction about the diaphragm. This increases gradually, all the voluntary muscles are thrown into a state of fixed spasm, and he gets tetanus. Here a few trifling branches of the digital nerves are injured, the morbid action is conveyed from them along the nerves of the arm to the spinal cord and brain, and is thence, by a reflex action, propagated all over the body. A wound of the finger causes a morbid action in its nerves, and it has been acknowledged by pathologists that this, by acting on the brain and spinal cord, may give rise to a general morbid action of the muscular system. This being the case, there is nothing improbable in supposing that a cause affecting any portion of the branches of the nervous tree, and which produces effects of a paralytic nature, may likewise react backwards towards the nervous centres, and thence,

by a reflex progress, may extend its influence to distant parts of the circumference.

To give another instance: how often do we see irritation, commencing in the intestinal mucous membrane, propagated backwards towards the brain? Take the familiar example of intestinal worms. A child labours under worms;—here the irritation of the digestive mucous surface whether it be produced by the worms or by the indigestion which accompanies them, is propagated from the stomach and bowels to the brain, and thence reflected to the voluntary muscles, causing general convulsions.

Dr. William Stokes details the following case in his lectures. "A young woman was admitted into one of the surgical wards of the Meath Hospital, for some injury of a trivial nature. While in the hospital she got feverish symptoms, which were treated with purgatives consisting of calomel, jalap, and the *black bottle*, a remedy which deserves the name of coffin bottle perhaps better than the pectoral mixture so liberally dealt out in our dispensaries as a cure for all cases of pulmonary disease. She was violently purged, the symptoms of fever subsided, and she was discharged. A few days afterwards her mother applied to have her re-admitted, and she was brought in again, and placed in one of the medical wards. Her state on admission was as follows:—She had fever, pain in the head, violent contractions in the fingers, and alternate contraction and extension of the wrist and fore arm. These muscular spasms were so great, that the strongest man could scarcely control the motions of the left fore-arm. In addition to these symptoms, she had slight thirst, some diarrhœa, but no abdominal tenderness. On this occasion a double plan of treatment was pursued, the therapeutic means being directed, to the head, in consequence of the marked symptoms of local disease of the brain, and to the belly, from the circumstance of abdominal derangement observed in this and her former illness. She died shortly afterwards, with violent spasms of the head and fore-arm; and as she had presented all the ordinary symptoms of a local inflammation of the opposite side of the brain, we naturally looked there first for the seat of disease. After a careful examination, however, no perceptible trace of disease could be found in the substance of the brain, which appeared all throughout remarkably healthy. She had all the symptoms which, according to Serres and Foville, would indicate disease of the optic thalamus or posterior lobe of the opposite side, yet we could not find any lesion whatever of its substance, after the most careful examination. But on opening the abdomen we found evident marks of disease; *the lower third of the ileum, for the length of six or eight inches, was one unbroken sheet of recent ulcerations.*" This case, gentlemen, you will perceive just now, bears very strongly on the subject of paraplegia arising from enteritis.

Again; how often do we see convulsions

brought on in the same way by cutaneous irritation? A child gets an attack of fever, accompanied by general irritability and restlessness. During the course of the disease, the lungs become affected, and the medical attendant applies a large blister, which is left on for several hours. Next day the symptoms of nervous irritation become more violent; the child is perfectly restless, or, if it doses for a moment, awakes screaming, and is finally attacked with general convulsions. Many other examples could be brought to support this view of the question, and prove that morbidly increased action of the whole muscular system may be excited by a cause acting merely on some insulated portion of the nervous extremities.

I think, therefore, that I am borne out by analogies strikingly exhibited by numberless examples, in asserting that the circumference of the nervous system has been too much neglected by pathologists, in their explanations of the nature and causes of paralytic affections. I could give many instances of pains commencing in particular parts of the body, and travelling back towards the spine, so as to give rise to an affection of that organ, which has been too generally looked upon as the result of idiopathic disease. How often does this happen in hysteria? How often does it happen that the organ principally engaged in hysterical cases becomes, during the attacks, acutely painful, and that, as the disease proceeds, the pain travels back towards the spine, until at length the spinal cord itself becomes affected, and we find acute pain and tenderness over some portion of its track? I am fully persuaded that many modern authors who have ascribed the phenomena of hysteria and other affections to spinal irritation, have been too hasty and indiscriminate in their explanations. In the majority of cases you will find hysterical patients complain at first, not of pain in any part of the spinal cord, but in the right side in the situation of the liver, in the region of the heart or stomach, or in the head or the pelvic region. At this period there is seldom any tenderness over the spinal cord; but, as the disease goes on, the irritation which existed in some of those situations to which I have referred, is extended to the spine, and pain and tenderness are now felt over some of the spinous processes of the vertebræ. When this has taken place, then the spinal irritation thus produced becomes itself a new cause of disease, from which, as a centre, the morbid influence is propagated to other organs. The profession owe much to Teale, Griffin, and other writers, who have pointed out the importance of attending to this spinal tenderness in cases of hysteria, &c. Still, however, like all those who have been employed in investigating a new subject, they have perhaps generalised too hastily, and have, in many cases, regarded this spinal tenderness as a cause, where it should have been merely considered as a consequence.

Having thus endeavoured to explain some of the general principles which should guide us in the investigation of nervous diseases, I shall relate some cases of paraplegia, which, though differing in their origin as to the organ inflamed, will strike you as exhibiting a close analogy to those published by Mr. Stanley. "In November, 1832, I attended with Mr. Kirby and Mr. Cusack a young gentleman aged fourteen, who was residing at a boarding school in the vicinity of Dublin. He had eaten a large quantity of nuts on the eve of Allhallows, and had, in consequence, obstruction of the bowels, attended with sense of weight and pain of the stomach, nausea, loss of appetite, and obstinate constipation. Active purgatives, of different kinds, were employed without effect, and the obstruction was only removed by the use of repeated enemata thrown up with Read's syringe introduced as far into the cavity of the intestine as the circumstances of the case permitted. To these means, assisted by leeching and stumping, the constipation yielded; but its removal was followed by symptoms of enteric inflammation, embracing not one but all the coats of the intestine, the mucous, the muscular, and certainly the peritoneal. The occurrence of a new and violent disease greatly impeded his cure; we had a long and anxious attendance, and the young gentleman escaped with great difficulty. However, the enteric symptoms at length gave way, convalescence became manifestly established, the patient was able to sit up in his bed, and as his strength and appetite were rapidly returning, he was informed that he might get up. On attempting to leave his bed, it was found that he had lost the power of using his lower extremities—in fact, he had become paraplegic. He had perfect power over his arms and trunk, but the lower extremities were quite useless. The paralysis, however, was entirely limited to the muscles; there was no diminution of sensibility in the limbs; no numbness, pain, or sensation of formication; and the muscular functions of the bladder and rectum were, apparently, uninjured.

Before I enter on the explanation of this case, permit me to recite the following. "In the month of November last, I was called to visit a lady residing in the neighbourhood of Merrion-square, who was said to be labouring under symptoms of dyspepsia. She had a sense of weight about the stomach, nausea, tendency to vomit, epigastric and hypochondriac tenderness (the latter situated in the right side) but no fever or excitement of the circulation. In the course of two or three days she became slightly jaundiced, and it was evident that the latent cause of her disease was, in all probability, a gastro-duodenitis terminating in an affection of the liver. It is sufficient to say that this lady's symptoms went on, and that the diseased action gradually extended to the whole intestinal tube, liver, and peritoneum. Her bowels became tympanitic, her

belly extremely tender on pressure, she got low fever, with quick pulse and great restlessness, and was saved with difficulty by the repeated application of leeches, and the use of calomel so as to affect the mouth. She became convalescent, but with the return of health it was found that she had lost the power of using her lower extremities. She still continues paraplegic.

In the case of the young gentleman already detailed, you will recollect that the paralysis was entirely limited to the muscular functions of the lower limbs, and that there was no derangement of sensation, no lesion of the muscular powers of the rectum and bladder. The same thing occurred in this case. There was in the beginning no impairment of sensibility, and the power over the rectum and bladder was uninjured. "Within the last three weeks, however, she has complained of pain in the loins and bowels, and the muscular functions of the bladder are becoming deranged*." Indeed the case is rather unfavourable; it has resisted the ordinary remedies, and threatens to become one of confirmed paraplegia. It is to be observed that in this lady the loss of power was much more complete than in the young gentleman before referred to; his paraplegia was by no means perfect, and yielded to the employment of stimulating frictions to the extremities, combined with a cautious use of internal stimulants and tonics. In neither of these cases was the loss of muscular power so great as to deprive the patients of the use of their legs, while lying in bed. They could then be raised, flexed, and extended with apparent ease and strength, and yet when the patient attempted to stand up or walk, he was totally unable to do either, his legs sinking under him, and even when supported by a person at each side, so as to take the greater part of the weight of the body off the limbs, he was still unable to advance one foot before another. I cannot understand why so great a difference should exist between the muscular force of the legs in the one position and in the other.

Here you perceive, gentlemen, we have more or less complete loss of power of the lower extremities supervening on inflammation of the gastro-intestinal mucous surface. Of this I have now witnessed several examples. How are we to account for this? In what way does paraplegia arise from inflammation of the bowels? The mode in which I would explain this phenomenon is as follows. The impression made by inflammatory derangement on the nervous filaments distributed to the mucous coat of the intestines is propagated to the spinal cord, and from this reacts on the muscular functions of the lower extremities. It is true that the intestines and most of the abdominal organs are almost exclusively supplied with nerves from the great sympathetic; but you are to recollect that these communicate by

numerous branches with the spinal nerves, and that, consequently, morbid impressions made on their extremities may be rapidly and extensively propagated to the spinal cord, and from thence by a reflex action to the muscular nerves of the lower extremities. When I first met with cases of paraplegia after inflammation of the bowels or fever with gastro-enteric symptoms, I thought that, owing to some peculiarity in the case, the great lumbar nerves had become implicated in the disease, that there was an actual inflammatory state of the neurilema, accompanied by thickening and effusion, which by compressing the nervous matter gave rise to the paraplegic symptoms. A more extensive review of the subject, however, has convinced me that this is not the fact, for, if it were, the affection of the nerves would naturally be attended with acute pains shooting in the direction of their course, for, as far as my experience goes, in every instance of inflammation attacking the neurilema, intense pain is felt in the parts to which the branches of the affected nerve are distributed. Again, though this explanation might apply to cases in which the inflammation was general, as where enteric is combined with peritoneal inflammation, it would not apply to those cases in which the inflammatory action is localised. Thus, in Mr. Stanley's cases, the paraplegia supervened on inflammation principally limited to the kidneys. In seven cases detailed in Mr. Stanley's paper, we find paralytic symptoms produced, not by any derangement commencing in the brain or spinal cord, but in consequence of an irritation having its seat and origin in the kidneys, and yet, in the majority of his patients, the paraplegia was as complete as if it had been produced by idiopathic disease of the cord or its investments. What was equally remarkable, many of those cases were accompanied by spinal tenderness, so that the most experienced practitioners on a review of the symptoms were inclined to look upon them as cases of disease affecting the vertebrae, or the spinal cord and its sheath. Yet on dissection there was no caries of the bones, no destruction of ligaments, no remarkable vascularity, softening, or suppuration of the spinal cord, no inflammation of its membranes, or effusion into its sheath. In almost all, the morbid phenomena were confined to the kidneys; there were depositions of pus dispersed through their substance, and the mucous lining of the infundibula, ureters, and bladder, was thickened and vascular. The formation of purulent matter was not, however, connected with the paraplegia further than as being, like it, produced by the same cause, inflammation of the kidney. In one case the paraplegia was very complete, and yet the inflammation of the kidney had not advanced to the stage of suppuration.

There can be little doubt that others have frequently noticed the occurrence of paraplegia after inflammation of the bowels, although no

* This sentence was inserted on the 23rd March, 1835. Mr. Carmichael and Dr. Nalty have seen this lady repeatedly.

author has as yet written upon the subject. It is well to be acquainted with the occasional occurrence of so untoward and obstinate a sequela of enteric inflammation, in order that we may watch attentively the state of the lower extremities immediately after the inflammation of the bowels has been subdued. As the patient in such cases has no pains in his limbs, and is not conscious of any loss of power until he attempts to stand up, and as this attempt is not usually made for many days after the subsidence of the inflammation of the bowels, in consequence of the great debility which the disease and the active treatment necessarily resorted to produce, this variety of paraplegia is very liable to be overlooked in its commencement, and is thus neglected at the very period when treatment is most likely to prove beneficial. The foregoing observations have, no doubt, excited a suspicion in the minds of some of you, gentlemen, that the paralysis so often observed to follow painter's colic may be derived from a reaction of the nervous system of the bowels on that of the muscular system in general. Dr. Bright, indeed, has asserted that inflammation of the spinal marrow or sheath, as denoted by spinal tenderness, always precedes the paralysis produced by lead. It often does, but by no means constantly, for I have pointed out to you several cases in this hospital, in which not the slightest vestige of spinal tenderness could be detected either before the commencement or during the progress of the paralysis which so often follows painter's colic. I am not inclined to adopt the supposition that the paralysis in such cases is merely secondary, and the result of the intestinal irritation. I think it much more probable that it depends on the poisonous effects of the lead acting directly on the nervous system. The same observation applies to the paralysis which so often occurs as a result of large doses of arsenic. Orfila has remarked that some of the dogs he experimented on, and which narrowly escaped dying in consequence of large doses of arsenic, became, when they recovered from the immediate effects of the poison, permanently paraplegic. I look upon this paralysis as a direct consequence of the deleterious action of arsenic on the nervous system, and not as the result of the gastro-enteritis it invariably produces. The fact, however, is well worthy of attention that both arsenic and lead produce intestinal irritation in the first instance, and loss of muscular power in the second. A knowledge of this fact will prepare us for understanding the connexion which appears to exist between intestinal irritation and paralysis.

In a lecture published by my colleague, Dr. William Stokes, in the 137th number of the *London Medical and Surgical Journal*, he makes the following observations, which I shall beg leave to quote:—"Here, then, we have well-marked paraplegia without any perceptible organic change in the spinal cord or its investments, but presenting distinct traces

of disease in the kidneys. This leads me to observe the very close connexion which exists between the kidneys and spinal cord, a connexion which has been long recognised by medical practitioners, but only in a limited point of view; for, though they were of opinion that disease of the kidneys and a discharge of ammoniacal urine were the results of spinal disease, they never seem to have reflected that the reverse of this might happen. It seems, however, now to be almost completely established, that disease of the kidneys may produce symptoms which are referable to disease of the spine. Medical men have been too much in the habit of looking at this matter only in one point of view, they know that disease of the spine will produce disease of the kidneys, and here they stop; but it has been shown that the reverse of this may happen, and that renal disease may produce very remarkable lesions in the functions of the spine. Of this very curious occurrence we have many analogies in pathology. Thus, for instance, in several cases of cerebral disease, but particularly in hydrocephalus, we have vomiting; here we have functional disease of the stomach depending on disease of the brain. Take the reverse of this,—observe the delirium which attends a case of gastro-enteritis; here you have the functions of the brain deranged in a most remarkable manner, and this produced by sympathy with an inflamed mucous membrane. The truth is, that in the spine and kidney, as well as in various parts of the body, we may have two organs so closely connected in sympathy, that disease of the one will bring on serious functional lesion of the other."

It will be seen that these observations coincide in many points with the principles I have laid down in the published lectures which I delivered on the subject of nervous pathology, and to which I have already referred. On this point Mr. Stanley makes the following remarks:—"In reflecting on the phenomena of the first series of cases which have been detailed in this paper, it might be thought improbable that irritation commencing in the kidney or in the bladder should be propagated through sentient nerves to the spinal cord, and that the impression should thence be transmitted through both the motive and sentient spinal nerves to the limbs, here occasioning an impairment both of sensation and of the power of motion. Some illustration of this subject seems to be furnished by the researches of experimental physiology. If in an animal, a few seconds after it has been deprived of life, the spinal cord be then divided in the middle of the neck, and again in the middle of the back, upon irritating a sentient organ connected with either isolated segment, muscular action is produced, that is to say, a sentient organ is excited, and an irritation is propagated through the sentient nerve to the isolated segment of the spinal marrow, where it gives rise to some change,

which is followed by an impulse along the voluntary nerves to the muscles of the part*.' In the instances which have been adduced, irritation commencing in the nerves of an internal organ, the kidney, has been transmitted through the spinal cord to the motive and sentient nerves of the lower extremities; but the same phenomena may occur in an opposite order, as in the case of a compound fracture, or other severe injury of the lower extremity, followed by retention of urine from irritation arising in the anterior crural and ischiatic nerves, and communicated through the lumbar and sacral plexuses of spinal nerves to the nerves of the bladder. Extending these views to cases of neuralgia where there is no visible derangement of structure or other local cause of excitement, it will always be difficult to determine whether the source of irritation be in the affected nerves, or in the central portion of the nervous system whence they are derived."

You will perceive that this explanation, as far as it goes, though not in the same words, is in meaning the same as that which I have given, with this exception, that it is only a corollary of the general principles which I had laid down in my lectures on the pathology of the nervous system. Long before the publication of Mr. Stanley's paper, I had established the proposition that impressions made upon any portion of the nervous extremities may be propagated towards their centres, and thence by a reflex action transmitted to the nerves of other and distant parts, so as to give rise to morbid phenomena analogous to those which are produced by disease originating in the central parts themselves. Applying this principle to the subject of paraplegia, we shall find that, independently of cerebral or spinal disease, it may arise from a variety of causes, each referable to lesions commencing in distinct and isolated portions of the nervous extremities. Thus in Mr. Stanley's cases, the exciting cause seems to have originated in the urinary system; in the cases which I have detailed, where it supervened on inflammation of the bowels, it commenced in the digestive, and it appears, from a communication made to Mr. Stanley by Mr. Hunt, of Dartmouth, that the same thing may result from irritation existing in the uterine system. Mr. Hunt alludes to several cases of disease of the uterus being followed by such loss of power in the lower limbs that the patients were entirely confined to bed, adding that there was no change of structure in the parts to which the symptoms referred as the source of irritation. In addition to these, I shall in my next lecture bring forward several cases to prove that a similar loss of power may be produced by the action of cold on the lower extremities. Indeed, the number of cases which I have recently met with, where

paraplegia was evidently brought on by exposing the lower extremities to cold and wet, has very strongly directed my attention to this form of the disease, and I trust I shall be able at our next meeting to communicate some very interesting matter on the subject.

I shall conclude this lecture by reading the following case, for which I have been indebted to the kindness of my friend Dr. Hutton.

"Richard M'Nab, a sailor, aged 38, was admitted into the Richmond Hospital on the 16th of January, 1835, and placed under Dr. Hutton's care. His previous history was briefly as follows: in the summer of 1826 he strained his back in leaping, and was confined to bed in consequence of the accident, but recovered in about twelve days. Shortly afterwards he contracted gonorrhœa, which was attended with hernia humoralis; this yielded to repeated local bleeding, but a gleet remained, and this, after continuing for some time, disappeared under the use of sea bathing. He then enjoyed good health, with the exception of occasional slight pain in the lumbar region, until October 1830, when, being much exposed to cold and wet during a long and fatiguing voyage, he got an attack of piles, for which he was under medical treatment for seven months. During the continuance of this affection he first observed a frequency in micturition, but had no retention or sensible obstruction of urine. After recovering from the hæmorrhoidal attack, he enjoyed good health until September 1831, when, coming from Cadiz to the port of Dublin, in a very leaky vessel, he suffered greatly from cold, wet, and fatigue, being almost constantly engaged at the pumps, which could not be left for ten minutes at a time. In addition to this, being deprived of his usual allowance of spirits for thirty-two days, he found himself, on his arrival in Dublin, in a very weak state. He rested from his occupation for a fortnight after discharging his cargo, and states, that during this time he drank from four to six glasses of whiskey daily. He then went on board the Elizabeth of London, as chief mate, but, after eight or nine days, his back and lower extremities became affected with pain and weakness, which increased to such a degree that he was obliged to give up his occupation on the thirteenth day. He states, that during the time his back and legs were getting weak he was obliged to pass water about three times in an hour, which he did with pain and tenesmus. On the 1st of January the pain of his back was very severe, and he lost the use of his limbs, but not completely, for he could support himself, and even walk a little with the aid of two sticks.

"At the time of his admission he appeared somewhat broken down in his general health; he was pale, emaciated, and laboured under derangement of his digestive organs. He suffered from occasional chills, succeeded by heats and sweating, which occurred at irregular periods; he also laboured under micturition,

* Outlines of Human Physiology, by, H. Mayo.

dysuria, and the stream of urine was much diminished. The weakness and loss of power in his lower extremities as reported.

"His treatment was as follows:—First, cupping over the loins, then moxæ in the same situation; attention to his digestive organs; diluents and opiates for the urethral symptoms. On the 26th of the same month a very close stricture was found to exist in the membranous portion of the urethra. A small catgut bougie of double length was introduced, so that one half of it projected from the meatus; over this was slid a small gum elastic catheter of ordinary length, and open at each end, until it traversed the stricture and reached the bladder; the catgut bougie was then withdrawn, and the gum elastic catheter secured. A little constitutional disturbance followed, but soon subsided; and in a few days gum elastic catheters of a much increased size were introduced with facility.

"A very remarkable amendment took place in his back and lower extremities in a very few days after the first introduction of the instrument; in fact, it was almost sudden. Warm baths, friction to his limbs, &c., completed his cure. He was discharged on the 25th of February, at which time the power of his lower limbs was perfectly restored, and the symptoms affecting the urinary system had disappeared."

You at once perceive the extreme importance of this case, gentlemen. It bears directly on the question before us, and proves that urethral irritation may, as well as inflammation of the kidneys, give rise to paraplegia; and it affords another striking illustration of the general proposition which I have laid down.

LECTURES

ON

MIDWIFERY & THE DISEASES OF WOMEN AND CHILDREN,

BY EDWARD RIGBY, M.D., F.L.S.,

ASSISTANT PHYSICIAN-ACCOCHEUR TO THE
GENERAL LYING-IN HOSPITAL.

Delivered at St. Thomas's Hospital.

LECTURE XXVII.

Perforation—Artificial Premature Labour.

GENTLEMEN,—I have hitherto described to you those obstetric operations which are intended to preserve the life of the child as well as that of its mother; I now come to those where it is the painful duty of the practitioner to sometimes sacrifice the former in order to save that of the latter, or, in other words, I have now to offer you a few observations on *perforation* and *embryulcia*. Perforation is that operation where, by means of sharp instruments, we *perforate* the cranium, and thus, allowing the brain to escape, diminish the bulk of the head.

No part of the armamentarium *Lucinæ* is so rich in instruments as this, for in no operation has there been so many invented as for that of destroying the child. In former times, when turning the child and the application of the forceps were unknown, the only means of delivering the woman was by lessening the head, and bringing the child away by sharp hooks. The operation consists in introducing two or three fingers into the vagina to that part of the head where we intend to perforate, we then pass the instrument along them carefully, to prevent wounding the parts of the mother, and, having inserted it into the skull, we draw it partly out again, and, turning it the quarter of a circle, it is again inserted so as to make a crucial opening. To facilitate the evacuation of the brain, it will be advantageous to inject warm water through the aperture in the cranium; if this be forced up pretty briskly, it loosens the attachment of the brain, which, being mixed with the water, becomes more fluid and escapes more readily; hence the cranial bones collapse sooner. For this purpose I use a syringe with an elastic tube, about a foot in length, and having previously broken down the structure of the brain with the perforator as much as possible, I insert this through the opening, and pass it down to the base of the skull; the water completely dislodges the brain, and in proportion as you pump in the one you expel the other. This expedites and facilitates the process very considerably. When the bones have collapsed the forceps will no longer have any hold upon the head; we must therefore use a hook, which, although not sharp enough to injure the fingers, is still sufficiently pointed to hold fast when fixed into the base of the skull. The point of the instrument should be carefully guarded by a finger of the other hand, and, when fixed into the skull, this finger should be pressed against the outside, corresponding to the part where the hook is fixed in the inside; this prevents us running any danger of injuring the mother in case the instrument should slip; the other fingers and thumb should grasp the shank of the hook for better support; it will thus give us warning when the hook is about to slip, and serves to preserve our finger from being wounded.

The perforation is indicated, first, in all cases where the labour is dangerous for the mother, and where the antero-posterior diameter, although more than two inches and a half, is so small that the head which presents cannot be delivered by the forceps.

The perforation has been opposed by some authors as barbarous; thus the celebrated Professor Oslander declared that this operation was altogether unnecessary, for that in every case in which it was indicated, he was enabled to deliver the patient by means of his forceps. You will recollect that I described these forceps to you as being peculiar, not only from having no fenestræ, but also on account of their great length; he was thus enabled to employ

a degree of force which, in my opinion, nothing could justify. When once convinced of the child's death, where labour was at all difficult, or circumstances in other respects at all unfavourable, I should consider it just as barbarous not to perforate as to perforate where it was unnecessary.

The perforation is indicated, secondly, where the head is much larger than natural, as in hydrocephalus; here, although compelled to perforate, Osiander would not call it perforation, but *paracentesis*.

In former times, a great variety of instruments were used for the purpose of perforating the head; they were chiefly hooked or *unciformia*. Some have been made straight, some curved, more or less pointed, sharp or blunt, simple or double; some were scalpel or lancet-shaped, *cultriformia*; some, like the spatula minus of Albucasis, had quite a peculiar form.

The perforators which have been used in modern times are mostly scissor-shaped, *forficiformia*. La Motte, Giffard, and Ould used common scissors, and Ræderer, in case of necessity, frequently used a strong pair of scissors. Among the perforators of this sort, those of Bing, Smellie, Levret, and Denman deserve particular notice. The scissor-shaped perforator has this advantage, that it can be protected by the hand alone, and introduced up the vagina without any danger of hurting the mother, and a sufficient opening made for evacuating the brain. The perforator of Smellie has the cutting-edge on the inside, precisely like a pair of scissors, the outer edges, which are neither exactly sharp nor blunt, have two projections or shoulders to prevent the instrument from passing in too far. Of this you will find an engraving in his last plate. The perforator of Levret and Denman has the outer edges somewhat sharp, the inner ones lying flat upon each other. Bing, of Copenhagen, had the merit of first inventing this perforator, but, having been adopted by Levret, it always went by his name.

The operation of *embryotomy* is merely a degree further than the perforation, for here the child is brought away piecemeal. No peculiar instrument is necessary for this purpose. The perforator of Smellie is best adapted for opening the chest, because, being precisely like a pair of scissors, we can cut through the ribs and cartilages with it. The hook generally used is one which was originally invented by Smellie, but Stein has added a convenient handle, which enables us to have a much firmer hold: it has also a curve, which was said to have been given to it by Levret, but this is doubtful, as Smellie himself has described it as curved. It is neither exactly sharp nor blunt, for, although it is not sharp enough to cut, it nevertheless is sufficiently pointed to hold.

Hitherto all perforators were either *unciformia*, *cultriformia*, or *forficiformia*. In later years, Assalini, and Joerg of Leipzig,

each invented, at the same time, a trepan-formed perforator. Assalini's consists of a steel barrel with a trepan at the end, through which passes a steel rod, at the extremity of which is a screw. When the instrument is introduced against the spot where it is intended to perforate, the screw is first fixed into the cranium, and a circular piece sawn out, which is brought away by the screw which is fixed to it. Joerg's is nothing more than a common trepan sliding in a metal sheath. Both instruments are useless, for they do not fulfil one chief object of perforation, namely, splintering the bones of the cranium. This has been objected to by some, on the score that the sharp angles and edges are liable to injure the soft parts of the mother; but there is no fear of this so long as they are covered by the cranial integuments. Assalini has also invented a species of forceps for cases where the antero-posterior diameter is less than two inches and a half, by which we may be enabled to turn the basis crani and bring it away obliquely, as Dr. Osborn is said to have done in the case of Elizabeth Sherwood. The forceps do capitally well on a skeleton pelvis: they have only one fault, gentlemen, namely, that they are quite inapplicable on the living body. When Mauriceau perforated, he first used an instrument shaped like a spear head, with which he made the opening, and then introduced a peculiar species of extractor, for which I must refer you to his work. In Aitken's Principles of Midwifery you will find a great number of different instruments described which had been used for perforation. The late Wigand of Hamburg was in the habit of using rather a peculiar-shaped perforator: it consisted of a long curved piece of steel, at the end of which was a sheath like a spear or serpent's head. By pressing a button in the handle a broad lancet rose out. It is an extremely dangerous instrument, and from merely perforating in the sutures or fontanelles, could not fulfil all the purposes of perforation. As soon as the bones began to collapse they would overlap each other and thus close the opening; hence the most favourable place for perforating is the parietal bone, for you not only make an opening which cannot possibly be closed in the manner I have just mentioned, but it is reached more easily than any other part of the head, because, as you all know, this is the part which presents. The late Ræderer when performing *embryulcia* used a curved bistoury, to which were attached two rings so as to fit upon the finger, and be thus introduced into the vagina; but this is also extremely dangerous, and can scarcely avoid injuring the mother. I am rather inclined to doubt if this be an original invention of Ræderer, because Spence, in his midwifery work, mentions that Dr. Simpson, a physician at St. Andrews, some time before 1751, proposed an instrument, called "the ring scalpel" for opening the head of the child.

The common perforator of the present day

is that which was first used, in this country, by Orme and Denman: the blades are short, but the handles are long, and by thus forming a long lever enable us to open them with greater facility when the instrument has entered the head. One disadvantage is, that we cannot open them merely with the finger and thumb of the hand which holds them, so as to enlarge the opening sufficiently. Professor Naegele of Heidelberg has therefore made the hinge so, that when we press the handles together the points open. The hand can act here with much more power, and we need never take the finger of the other hand away from the head of the child to assist in opening the points of the perforator. Mr. Weiss has also invented a perforator on a similar principle. When the brain is evacuated, the forceps, from the collapsing of the cranial bones, will no longer hold; this we also occasionally meet with in cases of difficult labour. We are sent for, and find that a practitioner has already made several attempts to deliver with the forceps. On applying them ourselves, we find that they are introduced easily enough, but will not hold; this results from the cranial bones having been broken and splintered from too much violence having been used. It would perhaps be as well to have a pair of forceps for these cases, the blades of which come closer than common. A variety of what have been called *craniotomy forceps* have been used of late years; those recommended by Dr. Conquest appear to be the best; but I do not think that they are often required, for if the brain has been properly evacuated in the manner I have described, the bones collapse sufficiently to allow the head to pass.

From the aversion which we must naturally always feel towards perforation, and from the unsuccessful results of so many cases of Cæsarean operation, an operation which has been justly held in the greatest dread by accoucheurs, necessity has driven them to devise all sorts of methods by which they could by any means avoid putting the operation into practice. Among them, the *partus arte prematurus*, or labour prematurely induced by artificial means, deserves your particular notice. It consists of inducing, artificially, the action of labour before the foetus is fully developed, but yet old enough to support its existence separate from the mother, in cases where we have reason to fear perforation, or at least so difficult a labour, that it is very doubtful whether the child can be born alive. We must not confound the artificial premature labour with the *accouchement forcé* of the French, where, in consequence of dangerous hæmorrhage from placenta prævia, or other causes, the os uteri has to be forcibly dilated and the child brought away—an operation now scarcely ever put in practice.

The premature delivery of the child has been more practised in this than in any other country, and was, I believe, first attempted by a practitioner named Jones, who, having

introduced a female catheter into the os uteri, ruptured the membranes, and waited for the pains. In Germany, Weidmann and Wenzel of Frankfort paid considerable attention to it, and in 1813 the latter eminent surgeon published several cases where the waters had been drawn off, and labour induced: these practitioners must be rather looked upon as exceptions, for almost all the other German authorities in the obstetric art were strongly opposed to it. Baudelocque also disapproved of it: the reasons which he assigned were, that we could never be certain of the time when it was proper to perform the operation, because there was no relying upon the correctness of a woman's reckoning; that the cervix uteri, in the seventh month, is seldom open, but is still thick, closed, and hard; that the pains or contractions of the uterus under such circumstances can only be induced by pretty strong mechanical irritation, and that, as this is merely artificial and not natural, the pains will frequently disappear the moment we cease to excite them by such irritation; that if the membranes be ruptured before the os uteri be sufficiently dilated, and the uterus active enough to expel the child, the pains will cease entirely, and the uterus having no liquor amnii to distend it, it contracts immediately upon the child, which becomes the victim to such treatment, &c. It is evident that when Baudelocque wrote this, he had the *accouchement forcé* before his eyes, where not a moment of time is to be lost, and from profuse flooding, &c. the patient is in imminent danger: this, however, is *not* the artificial premature labour.

Among his objections, Stein, jun., says, that the difference between the size of the child's head at the period which is fixed for inducing premature labour, and of one which has been carried the full time, is not sufficient to give any hopes of success. When Stein made these objections, he forgot the physical qualities of the cranial bones at that period, how soft and yielding they are. Oslander and Young were still more vehement against it, and abused it most violently.

It is to the late Dr. Denman that we are indebted for the first observations on this method of practice; and for a more particular account of his views on the subject, I must refer to his great work on midwifery. Since this time, an excellent monograph has been published on the *partus arte prematurus*, by Reisinger, in which, besides his own valuable observations, he has collected everything of interest which had been published in England or Germany: those who so furiously opposed it gradually became silent, and during the last few years it has been practised with great success.

Experience has shown that it was not necessary to induce labour at so early a period as was first imagined, on account of the very great difference which even one or two weeks are found to make in the hardness of the foetal skull; thus, for instance, in cases where the an-

tero-posterior diameter was only three inches, six weeks before the usual term of utero-gestation were found sufficient; and where it was three inches and a half, fourteen days made sufficient difference in the foetal skull. After the rupture of the membranes it may be twelve, thirty, or even sixty hours before any uterine action begins to be perceived, we should avoid any attempt to hurry the process, which should be as gradual as possible, and the patient should preserve a state of perfect quiet. Dr. Denman and Dr. Merriman have both remarked that, in a number of cases, a smart shivering fit and febrile attack had followed the operation, and sometimes even with slight delirium; and in many cases which have terminated unsuccessfully, and where a sudden fit of severe shivering had been observed, it was considered as a symptom of the child's death; and some practitioners actually tried by warm drinks, &c. to prevent it, as if this could preserve the child's life. We can scarcely, however, consider it as denoting the child's death, for, in two cases where this shivering was very severe, Professor Naegelé told me that he had seen the child born alive and healthy. In one case, where the febrile attack was very severe, Dr. Merriman gave a smart cathartic, with calomel, which, having brought away a large quantity of fetid dark-coloured *stercus*, produced much relief.

From the passive state in which the uterus is during pregnancy, and from the distance of the os uteri, it is frequently exceedingly difficult to pierce the membranes, as there is no contraction to press them against the os uteri. If the os uteri be not low enough in the pelvis to perform this operation conveniently, Dr. Haighton recommends us to direct the patient to strain and bear down; but this end can be equally well attained by binding a broad bandage tight round the abdomen. The instrument which my friend, Dr. Hugh Ley, uses for this purpose is very convenient: it is a common male catheter, slightly curved and perforated at the extremity, so as to permit of a stilet to be pushed out. After puncturing the membranes, a warm dry cloth should be placed against the pudenda to receive the liquor amnii, and the patient should preserve a state of perfect quiet for several hours.

It is evident, in cases where the membranes are merely ruptured, and the water evacuated, that as the inferior segment of the uterus is not yet sufficiently developed or dilated, it must oppose a considerable obstacle to the passage of the head, and hence prove unfavourable to the life of the child. Professor Kluge, of the Charité at Berlin, tried a sponge tent, in order to dilate the os uteri, and thus hasten labour; but, as soon as the uterus begins to contract of itself, its inferior segment yields spontaneously. Our object, gentlemen, is not to deliver the child as soon as possible by main force, but to excite the uterus to contractions, and thus induce a natural labour, in which the child may be born alive; hence

Carl Wenzel has recommended not to let off the liquor amnii *at once*, for the slower this is done, the greater are the chances of a successful result, for by this means the *gradual* evacuation of the liquor amnii makes the artificial premature labour resemble natural labour still more, and the contractions of the uterus act more gradually upon the foetus, and with less violence.

Professor Naegelé has observed, that where the artificial premature labour had been once induced, the uterus frequently shows a disposition to expel its contents in succeeding pregnancies at the same time. Mr. Barlow has also noticed this fact in his third case (published in the eighth volume of the *Medical Facts and Observations*, 1800); where six children had been born by means of premature labour artificially induced, he mentions that in one of these labours the pains had come on spontaneously at the usual time at which, in the preceding ones, the membranes had been punctured. In his fifth case, where four children were thus born, the last labour came on spontaneously at the seventh month. In most cases the secretion of milk has followed as after a regular labour; this is a great advantage, for the thin imperfect secretion at this early period is much better adapted to the weak digestive organs of the premature born child; it is seldom that we can get a child under these circumstances to take the breast at first, and this is the chief reason why their digestive organs become so soon deranged, and why premature children are apt to pine away. In case no milk be present, a good substitute will be made by beating up fresh eggs and milk, boiling them over a gentle fire, and straining off the thin fluid.

It seems a little singular that practitioners should have never thought of exciting the activity of the uterus *before* they ventured to puncture the membranes, for when once a contraction has been induced they become instantly tense, and can then be ruptured with perfect ease and safety; the secretion of mucus at this period of pregnancy is most remarkably abundant, and greatly facilitates the whole process. The upper part of the vagina and the os uteri are frequently felt covered with small round lumps or knots of what feels like soft fat; these are called the *ovula Nabothi*, and are merely little sacculi of transparent mucus, which exudes upon slight pressure. This fact has also been noticed by Mr. Marshall, who observed in every case of premature labour artificially excited, that as the labour came on a very considerable quantity of mucous fluid was discharged, which appeared to be a natural substitute for the liquor amnii, and which must greatly facilitate the process of expulsion. In cases of faulty presentation of the child, turning of course must be used, and under these circumstances it will prove highly unfavourable for the child; where the diminution of the pelvic diameters

is considerable, it is frequently accompanied with a considerable inclination of the pelvis and pendulous belly, both of which greatly increase the difficulties of this operation; in other respects, I cannot see why the *partus arte prematurus* should not be nearly as favourable as labour at the full term of pregnancy; it does not possess the unfavourable character of other species of premature labour, because the hæmorrhages which are so apt to attend them are never known to occur here, and the author of an excellent essay upon the subject in the *Journal Générale de Médecine*, Sept., 1827, speaks of it in very high terms. It is to my excellent friend and teacher, Professor Naegelé, that we are indebted for first practically demonstrating the advantages of exciting the contractions of the uterus before we punctured the membranes. The first case where he attempted this method, was a patient whom he had delivered by perforation in 1819; he then ascertained that the antero-posterior diameter of the pelvis was scarcely three inches; several children were born in a similar manner; being again pregnant, for the fifth or sixth time, he determined if possible to save the child by inducing premature labour. Five weeks before the full term of her pregnancy he ordered her to use the warm bath daily, and then have the abdomen rubbed for some time with opodeldoc; still further to induce uterine contractions, he made her sit over the steams of hot water; at last pains came on, they gradually increased, and a living child was born. Having read in an English journal that laxatives had assisted considerably in inducing contractions of the uterus, Professor Naegelé has used them, in combination with vapour-baths and other means, with good effect, but these cannot always be relied on, especially purgatives and laxatives, as is seen by the following case. "I had once a case, where, from the narrowness of the mother's pelvis, several children had been sacrificed from the severity of her labours. The parents being of the better class of society were extremely desirous that if possible one should be saved. The patient fancied herself this time larger than usual, and was under great apprehensions that the child would be too large to be born, even with the assistance of the forceps. I placed her for a whole hour in a warm-bath, and had the abdomen well rubbed with opodeldoc, but not the smallest sign of uterine contraction followed. I then gave her a strong dose of drastic purgative, which, although it was repeated until it produced colicky pains, excited not the slightest appearance of action in the uterus. I then tried a smart laxative and warm-bath at the same time, but was equally unsuccessful. Having wasted some time in these fruitless attempts, and as she had only fourteen days longer to go, I at last ventured to try the *secale cornutum*. I gave her fifteen grains of it early in the morning, and after a short time she experi-

enced a few slight pains; I repeated the dose, the pains became stronger, they quickly increased, and the child was born alive, and is now about three years old *."

Dr. Hamilton, of Edinburgh, excited the uterus to contract by introducing a female catheter into the os uteri, and separating the membranes from the womb to a considerable distance from its mouth.

The late Carl Wenzel, of Frankfort, asserted that his teacher, Weidmann, was the first in Germany to propose this operation, having pointed it out in his inaugural dissertation, entitled "*Comparatio inter Sectionem Cæsaream, et Dissectionem Cartilaginis et Ligamenti Pubis*," but the late Professor May, Heidelberg, in a dissertation published under his auspices, entitled "*De Necessitate Partus quandoque Prematuri Provocandi*," 1799, was not only the first to propose this operation, but also recommended exciting the contractions of the uterus by warm-baths, &c.

OBSERVATIONS ON A PECULIAR SPECIES OF DEFORMED FEMALE PELVIS.

BY FRANZ CARL NAEGELE, M.D.,

Professor of Midwifery at the University of Heidelberg, &c.

From the Heidelberg Clinical Annals,
Vol. x. No. 3.

COMMUNICATED BY EDWARD RIGBY, M.D.

THE peculiarities of this species of deformed pelvis which I am about to describe, are, according to my observations, as follows:—

1st. That the pelvis appears awry, so that the symphysis pubis is pushed to one side, the sacrum to the other, these points of the pelvis not being opposite to each other, but oblique, and the entrance, cavity, and outlet of the pelvis contracted in the direction of one oblique diameter, and not in the direction of the other, but in cases of considerable deformity, even wider than natural, so that the superior aperture and cavity of the pelvis exhibit the appearance of an oval directed obliquely to one side, its shortest or transverse diameter corresponding to one oblique diameter of the pelvis, its long diameter to the other.

2nd. That the sacro-iliac sychondrosis, towards which the small end of this oval is turned, has become completely ossified, so that at this point scarcely a trace of the former mode of connexion is to be perceived.

3rd. That the side of the sacrum which corresponds to this spot appears destroyed or not properly developed.

4th. That the symphysis pubis is inclined to the opposite side to where the sacro-iliac sychondrosis is ossified, whereas the sacrum appears bent in the contrary direction.

* MS. Lectures.

5th. That the lower part of the pelvic cavity converges somewhat in an oblique direction.

6th. That the anterior half of that os innominatum, on the side where the ossification is, displays a much smaller degree of curvature than is observed in a well-formed pelvis, being much flatter, so that its surface is nearly plane, and if a line be drawn on this side of the brim, from about the middle, or (viz. in more aggravated cases of this deformity) even from the posterior extremity of the linea innominata, and behind the body and crest of the os pubis, up to the symphysis, it will be found to run nearly in a straight direction. I have never observed this in a pelvis of this sort, where the side was curved inwards.

The necessary result of this distortion is that the acetabulum on the flattened side is situated more anteriorly than is the case in a well-formed pelvis, whereas the other is turned quite outwards, so that, in taking a front view of the pelvis, we look directly into one acetabulum, whereas the other is either quite out of sight, or merely a small portion of its cavity visible. It may be observed, moreover, that the length of the os ilium on the side which is ossified, viz. between the anterior and posterior superior spinous processes, is less than that of the opposite side, the whole os innominatum of which presents no deviation whatever from the usual form.

With respect to the strength, colour, structure, &c. of the other bones of this species of deformed pelvis, no difference could be observed between them and the bones of young and perfectly healthy subjects; not a trace, either in form or other respects, could be detected of those changes which usually result from rachitis or mollities ossium, and, but for this distortion, and some other slight irregularities which required close inspection to detect, these pelves would have been looked upon as well shaped, and of sufficient capacity.

In two of the cases which have come under my immediate observation, no distortion of the spine existed; in two, however, the lumbar vertebræ are twisted, one towards the left, where the right sacro-iliac synchondrosis was ossified, the other towards the right, where ossification had taken place upon the left side. (See Cases 5 and 9.) What the condition of the superior portion of the spine was in these two cases, I had not the means of ascertaining. In Case 9, the distortion was so slight as not to have attracted notice. In four cases, (the particulars of the others I do not know) the anterior surface of the lumbar vertebræ is turned somewhat to the same side on which ossification of the sacro-iliac synchondrosis had taken place.

In none of the cases, the particulars of which have come to my knowledge, has there been any trace of rachitis, nor have any of the symptoms, appearances, and morbid changes been observed which characterise mollities ossium coming on after puberty.

None of the cases have been traced to the effects of external violence, as falls, blows, &c., nor has there been any complaint of pain in the region of the pelvis, inferior extremities, &c.

Nine cases of this species of deformed pelvis have come under my own immediate observation, besides those which have been mentioned to me at different times by practitioners who, without having been previously aware of this peculiar deformity, had, in consequence of my mentioning it to them, recollected that they had either seen or possessed pelves of a similar kind. These pelves only differ from each other in the degree of contraction, and in the side at which the sacro-iliac synchondrosis is ossified; in all other respects they are as like each other as possible*, so much so that a person who is not aware of it, and has seen a pelvis of this sort, is half inclined to suppose, when he meets with a similar pelvis elsewhere, that it must be the same which he had seen before. This remarkable similarity would lead one to suppose that the cause or origin of this deformity was subject to some peculiar law. But, before proceeding further, let me call the reader's attention to the following description of these pelves:—

The two first I saw, in 1803, in my native district with a medical friend, in whose practice one of them had occurred. The patient was a healthy, robust, middle-sized peasant woman, æt. 19, in her first pregnancy. With the exception of the diseases of childhood, she had always enjoyed the best health, and had every reason to expect a favourable labour. The patient had had pains thirty-six hours when he was called, and the membranes had ruptured twenty two hours. He found the head still very high, and tightly fixed in the superior aperture, although the pains had continued severe since the rupture of the membranes. He at last succeeded in fixing the forceps, although their application was attended with considerable difficulty, and they had slipped several times. Still, however, he was unable to bring it further. He called in another practitioner, and, after considerable exertion, they at last succeeded in delivering the patient. The child, which had a considerable swelling of the cranial integuments, was dead, and the mother died on the fourth day after of abdominal inflammation. On the left side of the pelvis there was no trace of sacro-iliac synchondrosis to be seen; the left half of the sacrum was destroyed; the left oblique diameter of the brim was 4" 5"', the right 3" 4"'; the symphysis pubis was pushed over to the right side, and the anterior half of the left side was flatter than it is in a healthy pelvis; the other pelvis was exactly similar, except that the left oblique diameter measured

* The characteristic German expression is "wie ein ei dem andern," as one egg is to another.

4" 7", and the right only 3"; the inner surface of the left os innominatum, as far as this influences the form of the pelvic cavity, was much flatter than in the other specimen. Of the history of this case nothing was known beyond that it had been a young primipara, in whom perforation had been required before she could be delivered and who had died twenty-four hours afterwards.

The third case which I myself had the opportunity of observing is as follows:—

A blooming healthy brunette, æt. 19, rather above the middle stature, slender, and well made. It struck me as we carefully watched her when walking that she limped slightly, as if the left leg was somewhat shorter than the right, but it was not observed by the others who were present at the examination, and her parents and the rest of her family assured us that they had never perceived the smallest sign of lameness. She had always enjoyed good health, was always cheerful, was fond of dancing, and lived in the simplest manner. From her earliest youth she had been accustomed to be a good deal in the open air of a salubrious and beautiful district, and had never been exposed to hard work or much bodily exertion; her parents and family were healthy, her mother was well made, and in the course of fifteen years had had twelve children, with easy and natural labours. Her father and one of her two brothers are remarkably tall; this brother, upon examination for a recruit, was found to have the right hip higher than the left, and was on this account consigned to the baggage department.

The patient had menstruated regularly from the age of sixteen; had of late years led a very dissolute life, and was now in her first pregnancy. Admeasurement of the pelvis, by means of Baudelocque's callipers, gave an antero-posterior diameter of full seven inches, in other respects, as she was rather fat, the external examination gave little information. Upon examination per vaginam, the head was not found low and pretty firmly fixed in the pelvis, as is the case with primipare, but it was high up, and very moveable; the promontory of the sacrum could not be reached either with one or two fingers; the membranes ruptured two days before her labour began. During the first day, the pains were weak, but on the following day they were disproportionately painful in comparison to their strength, although not lasting, and it was not until the third day of labour, that the head had so far entered the superior aperture as to make us suppose that the forceps might be safely applied; the extraction of the head by means of this instrument was so difficult, and required so much exertion, that we afterwards regretted not having perforated; the placenta was retained by stricture of the uterus, and after waiting an hour the appearance of hæmorrhage made it necessary to be extracted artificially. The child, which was

dead, was a male, and weighed *libj. 3xvss.*; the face was swollen and livid, and there were marks of putrefaction, especially upon the abdomen. On the following day the patient was attacked with symptoms of puerperal fever, with profuse diarrhœa, and died on the fifth day after delivery.

The post mortem examination showed nothing unusual in the cranial or thoracic cavities, except some considerable adhesions of the lungs, evidently of long standing. On opening the abdomen, the intestines were found completely covered by the omentum. The uterus, which was about the size of a full-grown fœtal head, presented no unusual appearances externally, except that its right angle was higher than the left: its substance, when cut into, appeared natural, nor were any marks of disease to be perceived upon its internal surface, or in the vagina; the broad ligament, the Fallopian tube and ovary of the right side showed marks of violent inflammation, being swollen, red, and the vessels minutely injected with blood. In this situation a considerable quantity of the usual straw-coloured exudation which is observed in puerperal fever was found, a portion of it under the form of coagulable lymph, but the greater part was fluid.

Description of the Pelvis, fig. 1.

At the first glance, the reader will see that the peculiarities in the deformity of this pelvis are precisely as described in the first part of this essay, with these exceptions—it has all the appearance of a roomy and (particularly as regards the strength, structure, and colour of the bones) well-formed pelvis of a young female: when dried and cleaned, it weighed, together with the three lumbar vertebrae which are attached to it, $17\frac{2}{3}$ $3\frac{1}{2}$ 3 . The left os innominatum appears as if pushed upwards and inwards, so that the crista of the ilium, the acetabulum, and tuber ischii of the left side are higher than those of the right. In like manner the spine of the left ischium is situated higher and more posteriorly than the right, and its distance from the transverse process of the first coccygeal vertebra is 9", whereas that of the other is 1" 9". A line drawn from the middle of the left linea innominata behind the body and transverse ramus of the left pubic bone, nearly up to the symphysis, diverges scarcely at all from a straight line. The breadth of the left os ilium, viz. from the anterior to the posterior superior spinous process is 5' 7", of the right, 5" 10". The distance of the right sacro-iliac synchondrosis, from the centre of the promontory, measures

* It is right to mention that I have omitted several of the more unimportant admeasurements, so as not to occupy too much room. The punctuation for inches and lines as in the original has been adopted for the same purpose.—*Tr.*

2" 2''; of the left, 1" 4''; the hollow formed by the anterior surface of the sacrum is natural; the distance from the centre of the promontory to the point where the body of the os pubis passes into its transverse ramus on the left side, is 1" 10''; on the right side, 3" 5''; the distance also of this spot from the anterior superior spinous process on the left side is 4" 1''; on the right side, 5" 2''. The right os innominatum, and right half of the sacrum, are well formed, except that this latter bone, which has four vertebræ, in the present instance has only three pairs of sacral foramina. The left sacro-iliac synchondrosis is completely ossified throughout its whole extent, nor are there any traces of a separation having formerly existed either anteriorly or posteriorly, so that both bones appear as one. The brim forms an oval, which runs diagonally forwards from left to right, the posterior extremity of which is formed by the left sacro-iliac synchondrosis, and its side by the body and transverse branch of the right pubic bone. The left oblique diameter, which may be looked upon as the great diameter of this oval, measures 4" 7'', the right 3" 5''; the shape of the cavity of this pelvis resembles that of the brim.

I am indebted to my much esteemed friend, Professor D'Outrepont, for the inspection of two other pelvis of this species; in the first (*fig. 2*), the *left* half of the brim and cavity is contracted, as in the three cases above-mentioned; the left sacro-iliac synchondrosis is entirely wanting, and the left side of the sacrum is also defective. The left oblique diameter of the brim measures 4" 4'', the right 3" 3''. Nothing further was known of the history of this case, beyond that she was a primipara, and had died after a severe instrumental labour.

The other pelvis (*fig. 3*) exhibits the same species of deformity, with the only difference that the distortion is in the contrary direction, the *right* sacro-iliac synchondrosis being ossified. The right half of the sacrum is defectively developed, and the symphysis pubis pushed over to the left side. The right oblique diameter of the brim measures 4" 6''; the left 3" 3''. A line drawn from the middle of the promontory to the spot where the body of the os pubis passes into its transverse ramus, measures, on the right side, 2'; on the left, 4''. The distance between the middle of the promontory and the anterior superior process on the right side, is 2" 11½''; on the left, 5" 2''. As far as one can judge of the two lumbar vertebræ which are still attached to the pelvis, the spine appears to have been curved to the right side, the body of the last lumbar vertebra being lower by nearly one half on the right side to what it is upon the left. Professor D'Outrepont has since informed me, he has been able to ascertain that it belonged to a primipara, æt. 20, in whose case Brüninghausen and Carl Caspar Siebold, having endeavoured to apply the forceps without success,

were compelled to perforate; but that, not being able to extract the head by means of the crotchet, the patient had died undelivered.

My friend and former pupil, Dr. J. H. Mencké, of Bremen, informed me that, in examining the museum belonging to Professor Billi, superintendent of the Lying-in Institution at Milan, he had seen two pelvis, which not only resembled each other remarkably, but were so exactly like one in my possession which he had often examined, that he could not help asking Professor B. how long he had had one of these pelvis; for he could scarcely believe that it was not the same pelvis which he had seen a little time before at Heidelberg. Dr. M. has for several years cultivated midwifery with great zeal, has devoted a good deal of attention to deformities of the pelvis, and merits the title of a well-informed scientific practitioner.

Last year (1833) my son Franz Joseph met with a pelvis in the Pathological Museum at Vienna, which in every respect resembles those above described. It belonged to a woman who had died in labour from rupture of the uterus. The ossification of the sacro-iliac synchondrosis, and diminution of the lateral half of the sacrum, &c., are here on the right side; the sacrum itself consists of five vertebræ. The spot where the sacro-iliac synchondrosis is ossified is quite smooth anteriorly and inferiorly; superiorly there is a slightly elevated ridge, which marks the former place of the synchondrosis. The left oblique diameter of the brim measures 3" 2'', the right 4" 10''. My son also met with another pelvis of the same sort during the present year (1834) in the museum of the Hospice de la Maternité at Paris. It was a case which occurred in 1822; the patient was brought into the Maternité, after having been in labour already four days, and the liquor amnii escaped for forty-eight hours. She died undelivered during the operation of perforation. The following description of the pelvis (*fig. 4*) was taken from the examination which my son made of it, and also from a cast in plaster which he sent me. This pelvis was more twisted to one side than any of those which I have described. The ossification of the sacro-iliac synchondrosis is on the left side. The symphysis pubis is pushed over to the right, the sacrum to the left side, the left half of which latter bone is wasted. This defective formation of one side of the sacrum is more marked than in any of the pelvis above described; so much so, that the bodies of the upper sacral vertebræ pass directly into the left ilium, and at this spot, which feels perfectly smooth, no trace can be perceived of a former separation. The right oblique diameter of the brim measures 3" 1'', the left 5" 1''. The distance between the centre of the promontory and the anterior superior spinous process of the ilium on the right side, is 5" 4'', on the left 3'. The sacrum consists of three vertebræ; its anterior surface from

above downwards is slightly concave. The anterior sacral foramina on the left side are smaller than on the right. As far as one can judge from the two lumbar vertebræ which are still attached, the spine appears to have had a slight curvature to the right side, and the body of the last lumbar vertebra is somewhat lower on the right side than on the left.

The cases which I have here brought forward appear to confirm a remark which I made in 1811 in my *Erfahr. und Abhandl.*, viz. that deformity of the pelvis from a mutual approach of the promontory and bodies of the two ossa pubis, takes place more frequently on the left than on the right side.

As to the origin: whether this malconformation and ossification of the sacro-iliac synchondrosis arises from some inflammatory process which had taken place in early life, the result of which had been the defective development of one side of the pelvis in this peculiar manner or degree, or whether any distortion of the spine at an early age, were the cause of this deformity, or whether it arose from some original defect of formation, &c., I am at present quite unable to say; further investigations are still required to ascertain this interesting point. It would be highly desirable that in the publishing of similar cases, as much as possible of the patient's previous history should be obtained, and that in examining the pelvis, attention should be also paid to the state of the spinal column.

The circumstance of not having been induced to pay much attention to this species of pelvic deformity until within the last seven years, in fact, until I met with a case myself, and not having had the opportunity of examining any large collection of preparations, and yet that nine cases should have come within my knowledge shows that it cannot be of great rarity. Whether Delpech, in his "Memor. des Hop. du Midi," alluded at all to this species, where he speaks of the frequency of oblique distortions of the pelvis, is difficult to say; but I have no doubt that the pelvis to which Dubois alludes in his Thesis for the Chair of Clinical Midwifery are of this species, as he had been informed of the fact by some of my own pupils, whom I had commissioned to make inquiries of him about pelvis of this sort, and to examine the collection at the Maternité. Moreover, if we recollect, in addition to the above remarks as to its frequency, that this peculiar species of mal-conformation may happen in persons who are otherwise perfectly well made, without a trace of rickets or osteo-malacia adult; and in cases where nothing had previously occurred which could produce any injury to the pelvis; when we recollect that the diagnosis of this deformity is rendered peculiarly difficult from the circumstance that examination per vaginam, or measuring the pelvis with Baudelocque's callipers, have little chance of giving a correct result; that no certain

diagnosis can be formed by external examination, especially where the patient is stout; when it is also recollected, that in all the cases which have come to my knowledge the lives of the mother and her child have been sacrificed; I am justified in saying that *it is a subject of the utmost importance in practice*, and deserves a place in our systems of midwifery as one of the causes of dystocia pelvica. No one can regret more sincerely than I do, not having been able to render these observations more full and complete; still I shall be glad if the little which I have now brought forwards will prove a means of inducing others, situated under more favourable circumstances for observation, to publish similar cases, and, if possible, to throw some light upon the origin of this deformity.

I look upon this paper merely as a short notice of the fact, and have therefore merely added outlines, showing the form of the pelvic entrance in certain cases. I intend to give this subject a much fuller consideration, and for this purpose have had the more remarkable pelvis drawn by an eminent artist. I shall collect whatever has been said on this subject by former authors, and shall feel greatly obliged to my professional brethren for the communication of any cases, remarks, &c., upon this subject.

Since the publication of this paper in the *Heidelberg Clinical Annals*, Prof. Naegelé has received a communication from Dr. D. D. Carlo Piantanida, Direttore dell' Ospedale maggiore, e dei Luoghi Pii uniti, at Milan, and Dr. Ambrose de Marchi Gherini, giving him a description of the pelvis mentioned by Dr. Mencké. Dr. Piantanida's description of one of the pelvis, which is in the Pathological Museum of the Ospicio de Sta Caterina alla ruota, marked 24, confirms the resemblance which Dr. Mencké observed to the pelvis described under Case 3, tab. 1, of the above paper, except that the Italian pelvis is a little more distorted. In the other case, which is marked 23, the peculiarities of this species of deformed pelvis (ossification of the sacro-iliac synchondrosis, defective development of one side of the sacrum, deformity of one of the ossa ilii, &c.) are on the *right* side; the left oblique diameter measures 2' 9", the right 5'. In both cases, the brim, from the ossified sacro-iliac synchondrosis, along the linea innominata, and behind the body and transverse ramus of the os pubis, forms nearly a straight line ("*descrive una linea quasi retta*"). Dr. Piantanida expressly mentions that the ossification of the sacro-iliac synchondrosis is complete in both cases.

e The Symphysis Pubis.

The coarse abuse with which the name of this justly celebrated accoucheur has been lately assailed by an English journal, is not a little derogatory to the character of the English medical public. Besides no slight ignorance of the subject, the author of the aforesaid abuse against Professor Naegelé has shown a singular want of judgment in venturing to rest his crude and incorrect grounds for vituperation on the fallacious medium of a French translation. If he had possessed even a moderate knowledge of the real nature of the case to which Professor Naegelé alluded, he would have found no lack of interesting materials; but, ignorant of what has been written on this subject in Germany and Holland during the last few years, he has ventured to accuse a distinguished individual of bad practice, before he himself was competent to form an opinion.

Not in pity, then, to him, but from a feeling of shame that the journals of my country

should go forth to the world with such exposures of ignorance, I beg to refer him to a case published in the *Medical Gazette*, for January 10, 1829, at the request of Professor Naegelé, by my friend Dr. Merriman, and also to a similar case, in the *Medical Gazette* for May 31, 1834, among my midwifery hospital reports.—E. R.

Reviews.

The Constitution of Man considered in relation to External Objects. By GEORGE CÔMBRE. pp. 440. Anderson. (HENDERSON EDITION.) 1835.

“The proper study of mankind is man.”

Of all the phenomena which can occupy the mind of the philosopher, there is not one so pre-eminent, not one which claims that high

interest in an equal degree to the present. Whether the subject be viewed in the abstract or in the manifold relations it has to health, to the comforts of social life, to the commerce between man and man, and to his future destiny, every other consideration sinks into the shade. The poet has appreciated its momentousness, the theologian has depicted it in glowing, but too often in darkened, colours, the gloomy mind has enshrouded it in dark and melancholic reflections, the pedant indulged in his satires on man, and the atheist endeavoured to cloud the "highest interests" of our being, and to envelop us in one impenetrable gloom. In the closet we are philanthropists or misanthropists, depending on our peculiar mood, or on our particular circumstances; now a declaimer against the structure of our minds, now in acclamation of their exaltation. But after all, after the flippant has expended his twice-told tale, and has ceased his impertinence, after the casuist has delivered his doubts, and the sophist has suppressed his revilings, to the identical conclusion all arrive,—let us have the greatest sum of happiness for the greatest number of individuals. How such a consummation is to be attained, affords a problem which, to solve in a rational manner, offers a theme for a million of minds, if, shall we say, cast in a million of moulds. We are not casuists, sophists, or deists—assuredly not atheists—but feel incompetent to solve the problem; its very momentousness overwhelms us; yet we forget not the principle affirmed, affirmed before, by the majesty of nations.

Such a work as the one before us affords us great delight. The notice which incited to the present edition of this book, already too little known, is one to which every individual will accord his approbation. The presentation of it in this particular form is dependent upon a liberal bequest of the late W. R. Henderson, Esq., younger, of Warriston and Eildon Hall, leaving in his deed of settlement, after paying certain annuities, &c., a sum of money for the execution of a production like the present, naming, however, the eminent and intelligent author, and the production before us, the testator's object being that knowledge be diffused in a cheap form through the people.

Despite all the objections that have been advanced against the truth of phrenology, despite the terse revilings of Jeffrey, and all polemical discussions that have occurred, we have here one of its applications to a purpose which the veriest sceptic or opponent could not do otherwise than applaud.

If phrenology have achieved no more for the public weal than being an incitant to productions such as this, which shall diffuse philosophy, unadorned with parade; theology, unfettered by prejudice; it would have been a sufficient guarantee for its promulgation.

Mr. Combe is not a profound thinker; his

inductions are not so rigorously exact as we should wish to meet with in works of this character; but he is obviously a man of observation, and one who can collect facts. As, however, this book is not strictly medical, but embraces the whole scope of philosophy, metaphysical as well as natural, and the major part being metaphysical, we shall not enter into any lengthened account of its contents. Its great object is to prove the harmony subsisting between all the works of nature; the importance of attending to organic laws, as influencing natural ones; the analogy existing between natural laws and vital; and to show the striking analogy in their operations, and the close dependencies they have upon each other;—a work, it must be confessed, almost superhuman. For us to demonstrate the performance of Mr. Combe, be it bad or good, would require a very long disquisition—would extend further than our limits will permit. We will, however, give a few isolated parts as fair specimens of the whole. The following are the contents of the book:—

“General View of the Constitution of Human Nature, and its relations to External Objects—On Natural Laws—On the Constitution of Man, and its relations to External Objects—On the Sources of Human Happiness, and the Conditions requisite for maintaining it—Application of the Natural Laws to the Practical Arrangements of Life—To what extent are the Miseries of Mankind referable to Infringements of the Laws of Nature?—On Punishment—On the combined Operation of the Natural Laws—Influence of the Natural Laws on the Happiness of Individuals—On the relation between Science and Scripture—Conclusion.—APPENDIX. Natural Laws—Organic Laws—Hereditary Transmission of Qualities—Laws relative to Marriage and Education in Germany—Death—Infringement of the Moral Laws.”

At page 128 are enumerated some of the calamities arising from the infringements of natural laws.

And after quoting some passages from Voltaire on the characters of the Apii and the Catos, in which are some eloquent and pithy remarks on the hereditary qualities of individuals, he observes, “Phrenology reveals the principle on which these phenomena take place. Mental talents and dispositions are determined by the size and constitution of the brain. The brain is a portion of our organized system, and, as such, is subject to the organic laws, by one of which its qualities are transmitted by hereditary descent. This law, however faint or obscure it may appear in individual cases, becomes absolutely undeniable in nations. When we place the collection of Hindoo, Carib, Negro, New Holland, North American, and European skulls, possessed by the Phrenological Society, in juxtaposition, we perceive a national form and combination of organs in each actually obtruding itself upon our notice, and corresponding with the mental characters of the

respective tribes; the cerebral development of one tribe is seen to differ as widely from that of another, as the European mind does from that of the New Hollander. Here, then, each Hindoo, Chinese, New Hollander, Negro, and Carib, obviously inherits from his parents a certain general type of head; and so does each European. If, then, the general forms and proportions are thus so palpably transmitted, can we doubt that the individual varieties follow the same rule, modified slightly by causes peculiar to the parents of the individual? The differences of national character are equally conspicuous as those of national brains, and it is surprising how permanently both endure."

These extracts afford a fair proof of the value of the book; and yet, to admit a paradox, they are no proof whatever. They are but stones taken from the walls of a building erected of the same material. It is an exceedingly valuable book; one which will have, we do not doubt, a more extensive sale than any work published at the present day. It is amply deserving of such a diffusion; not only from the very remarkable cheapness, but from the immense quantity of interesting matter it contains. The price would but pay for the paper, and the matter is worth ten times the price.

Principles of the Treatment of Gout, with a further Examination of the effects of Colchicum as a Remedy; and some Observations on the Use of Veratria in that Disease.
By Sir CHAS. SCUDAMORE, M.D., F.R.S.
Longman. 1835.

The author of the present pamphlet has been respectably known to the profession as a writer on gout for the last twenty years. His works have not altered materially the mode of its treatment, but they have, unquestionably, been the means of directing the attention of practitioners to more correct views of its origin—to the causes which induce it—than had been previously done.

Gout, it may be said, is connected with, nay, closely allied to, disorder of the digestive apparatus. Gout is clearly hereditary, in proof of which ample testimony can be adduced. But does it ever make its appearance without some obvious exciting cause?—probably not. The alderman, the pampered citizen, the epicure of course, and the indolent, are the victims of its ravages.

What is the nature of the affection? No one has ever answered the question satisfactorily: it is an affection *sui generis*; Sir C. Scudamore says it is. What is its nature—what its essence? Is it inflammation of one or more of the structures of the joints? of the skin? of the fibrous structures surrounding the joints, ligaments, aponeuroses, or tendons? of the synovial membranes, cartilages, or the bones? We do not know. It is better to confess ignorance than offer an opinion which has no other basis than conjecture. The treatment

which our author recommends, and upon which from an extensive experience he must be able to give information, shall suffice for the review.

Of Bleeding.—General bleeding is never to be thought of as a remedy for the local inflammation, which it does not tend to relieve as it does common inflammation; when that is connected with increased action of the heart and arteries. It was considered, formerly, that bleeding in part was improper, but this is an exploded error. If any important viscus be inflamed, whether in accidental connexion with the paroxysm, or otherwise; also if there be symptoms of congestion in any organ—in the brain more especially—blood should be taken away; also in general plethora, in conjunction with a strong pulse, bleeding may be practised with a view to lessen the quantity of the circulating blood. This method of practice is to be distinguished from the use of bleeding as a remedy for the gout in the extremities, which it would rarely tend to remove.

Local bleeding by leeches is not successful; it is often disadvantageous, and occasionally even injurious in acute gout, rather aggravating than relieving the pain. In some cases of chronic gout benefit arises from the application of leeches.

Of Emetics.—Sir Charles entertains a higher opinion than formerly of the advantages of producing free vomiting, and especially at the commencement of a severe attack. Unless there are peculiar contra-indications, he recommends this as one of the first measures to be adopted, particularly when the stomach is disordered, as it frequently happens. The operation of an emetic has caused immediate subsidence of gouty symptoms, and has occasionally succeeded in arresting a threatened paroxysm.

Of Cathartics.—When it is considered how almost wholly a fit of gout appears to result from congestion in the abdominal viscera, more especially from a surcharge in the circulation of the vena portarum, and of the biliary pores, we are at once led by theory to the choice of this class of remedies, and no less confirmed in its propriety by practice. If the alvine discharges exhibit an unnatural character, whether as to darkness of colour, which marks a vitiated state of the biliary secretion, or if, on the contrary, the appearance be that of clay, or of a leaden hue, proving torpor of the liver, the bowels must be acted on freely. The mercurial purgative is the best, by stimulating the excretory ducts of the liver. A combination of calomel and colocynth agrees with most persons, and a small dose of James's powder is often useful. With some, however, the pil. hydrarg. or pil. hyd. submur. compos. will agree better than calomel. It is better to administer the mercurial dose at night, diuretics and purgatives in the morning.

The employment of diuretics is also useful, such as the carbonate of potash, joined with the spirit of nitric ether and compound spirit

of juniper, to obviate the dense state of the urine, its deep colour, and the remarkable quantity of brick dust, or pinkish sediment, which sooner or later in the paroxysm it deposits on cooling.

The author has witnessed the most inconvenient consequences arise from the excessive action of mercury, with an aggravation instead of relief of all the gouty symptoms; he therefore advises that due care should be observed not to produce salivation, or go beyond just making the gums sensible of its influence in any case, and, in general, not to this amount.

Sudorifics.—During the course of acute gout, it is highly desirable that the functions of the skin should be duly performed; and when there is heat of surface, we should endeavour to procure free perspiration at intervals, and especially in the night; for in the day-time, when it is our still more important object to maintain a full action of the bowels, the action of sudorifics would be incompatible. Of this class of medicines tartarised antimony in combination with salines and Dover's powder is to be preferred.

Narcotics.—The author is a decided advocate for such employment of opiates as may be found necessary for the mitigation of pain, and the procuring of sleep at night. The preparations of opium appear to have the best effect.

Colchicum.—Sir Charles observes upon this remedy—"I am anxious, after many years' study, and observation of its properties and effects, to record my confirmed opinion. Its great value as a medicine is unquestionable; but I cannot hesitate to declare, that, in the injudicious manner in which it is popularly employed, it carries with it much more of bane than antidote."

He recapitulates the leading points on the virtues of colchicum in gout in the following words:—

"I now hear the question repeated, what final opinion is to be delivered to the gouty patient on the subject of colchicum? Is it to be taken from him altogether as a remedy for his sufferings, on the score of prudence? I answer, certainly not. I conceive, that, in the way of general instruction, the following positions may be laid down. Some of my former observations I must recapitulate. Inasmuch as the acetum colchici is very greatly the mildest form of the medicine, it is desirable to obtain from it, in combination with a saline aperient, those palliative effects which are to be expected from colchicum. When any nausea or inconvenience is experienced from the fluid form of the medicine, it may be given with advantage in the form of pill, the extract being used for this purpose, and other suitable medicine being joined with its use.

"Some individuals, it is true, derive every satisfaction from using the wine of colchicum, taking a moderate dose at bed-time, for two or three nights, and paying due attention to the functions of the liver, bowels, &c., by

means of other medicines. When gout not only readily yields to such treatment, but also does not return in a short time, I do not wish to offer any objection to this plan of treatment, much as I give the preference to my own method of using the acetum. As there is no general rule without its exception, so I may here remark, that circumstances may arise in which I should be disposed to give the wine; for example, when it may be necessary to avoid all excitement to the bowels, and when, at the same time, it is desirable to make the quickest impression on the gouty action and irritation.

"From all which I have stated, the reader will at once perceive, that I allow colchicum the claim of possessing a greater power in relieving the immediate symptoms of gout, than any other medicine which we obtain from the materia medica. This, however, is too commonly found to be only a palliative power; because it is not unfrequently seen that the paroxysm returns the sooner, in the direct ratio in which it is employed.

"In the manner in which I recommend the use of the acetum, the evil in question never follows in the same degree; and, generally speaking, the reproach is not at all deserved, because I employ it always in combination with alteratives, aperients, and other medicines, and desire to consider it as the auxiliary rather than the substantial remedy.

"The gouty paroxysm depends upon internal errors of the system, for which colchicum is not in any of its forms the remedy; and were it not that its palliative influence is so superior to that of any other medicine, I would never employ it in the treatment of gout. I would always prefer to remove the fit by other medicines, if I could succeed in a reasonable time; not because I view the judicious employment of colchicum as in any degree unsafe, but that I should expect the cure to be more lasting when its use can be omitted. Not only, indeed, does the gout return so much the sooner, and indeed with lamentable frequency, from the injudicious way in which colchicum is so commonly used, but, as I have already shown, the constitution becomes injured; this injury is manifested in various ways. Most commonly the mucous membrane of the stomach and intestinal canal suffers chronic irritation. The appetite and digestive functions are impaired; the patient loses flesh and strength; and the whole appearance alters. I have related examples of a fatal result. In other cases, the patient does not complain of loss of appetite, or indigestion, but still he loses flesh and strength, and fails in nervous energy. The medicine is exerting its unfavourable influence on the nervous system; and, according to my observation, materially impairs the functions of the liver."

In conclusion are the observations of our author upon veratria in gout. He confesses himself indebted to Dr. Turnbull for his know-

ledge of this remedy, and states that he has watched the operation of the veratria ointment, and is led to the conclusion, that no beneficial effects result from its application until the state of the constitution which gave rise to gout has been corrected by other measures. He objects to the employment of local treatment so early, especially in the form of friction, as recommended by Dr. Turnbull. When the acute symptoms have subsided, the veratria liniment he regards as a good application. He narrates five cases in which veratria was employed; he regards it "to be entirely a local remedy," producing no unpleasant constitutional symptoms, and its application affording pleasure to the patient.

Reports of Societies.

WESTMINSTER MEDICAL SOCIETY.

Saturday, April 11th, 1835.

PROFESSOR BURNETT, President, in the Chair.

DR. JOHNSON commenced the discussions, by detailing the case of a female patient, who was labouring under an extreme susceptibility of two of the senses, viz. sight and hearing; and, in order that no noise might be conveyed to the apartment, every avenue leading to the house was thickly strewed with straw, and every door was muffled, and every crevice capable of admitting the rays of light was carefully closed, by which means total darkness and silence reigned in the patient's apartment. The other senses are not affected. She can take mild nourishing food, without creating any disturbance; but all medicines produce an increase of her sufferings: even a few grains of rhubarb considerably added to them; but although she enjoys but little sleep, opiates are of no avail. The present attack has lasted six weeks, an interval of three months having elapsed since the first: both were produced by moral causes. In the former attack a degree of mental aberration existed, this phenomenon, however, has not manifested itself again.

Mr. Queade enquired if the functions of the stomach were well performed, and also in what state the different secretions were?

Dr. Johnson replied, that the bowels were rather torpid, as is usually the case when little food is taken; the other secretions were natural; her pulse was quiet; her tongue was moist; and the catamenia was regular. She was of temperate habits, and, when well, took horse exercise. He considered the case to be one of those multifarious forms of hysteria that the disease is capable of assuming.

The Doctor then drew the attention of the society to cases of a more practical nature, or at least as opening a more fertile field for discussion, than had come under his observation during the last few days, and which he be-

lieved were pretty prevalent just at this time viz. inflammation attacking the caput coli. Three cases were detailed, two of which proved fatal.

In the 1st case, a female, who had attended divine service on Sunday, after her return home was suddenly seized with pain at the situation of the caput coli; purgatives were administered, and early on Wednesday morning a copious evacuation of feculent matter from the bowels occurred, and afterwards the pain gradually increased, and the abdomen became gradually distended (ballonné).

In the second case, six or seven days had elapsed before any evacuation from the bowels could be solicited by the usual means, accompanied with agonising pain. When called in, he immediately prescribed general bleeding, local bleeding with leeches, and calomel and opium, so as to produce salivation, when copious stools followed, succeeded by recovery.

In the 3rd case, inflammation and obstruction at the caput coli were found on examination after death.

Dr. Johnson remarked, that in these inflammatory cases, if consulted early, and if the patients did not labour under any other causes that might tend to shorten or prove hazardous to life, his prognosis would be favourable, and the treatment that he would recommend from experience, should consist of active bleeding at the commencement of the attack, followed by calomel and opium, and the judicious use of laxatives.

Mr. Morris begged to know if any induration existed.

The answer was in the affirmative; and, in confirmation of the pathological change, the death and morbid appearances of the celebrated traveller Ballazoni were adduced, who died in this metropolis about eleven years ago. He remained seventeen days without any evacuations from the bowels being procured. Ballazoni had suffered severely from a similar attack while in Egypt. On opening the body, it was found that the obstruction had been occasioned by an internal hernia, which was formed in the following manner:—A blind pouch had been produced by two convolutions of intestines, that had become glued together through the result of a previous inflammatory process, into which aperture a knuckle of intestine had become strangulated, causing the impenetrable barrier to the passage of the contents of the canal.

The President solicited the attention of the members to the immense mass of speculative and practical matter that was now before them, trusting it would not fail to give rise to many valuable deductions. The case of hysteria, he said, vividly brought to his recollection that of a poor sufferer who had not spoken for upwards of two years and a half; but her sense of smell was so acute, that she was conscious of the approach of any food at a distance of two or more flights of stairs; and if even a grape was placed on the floor, or any other

part of the room, she would dart her fingers instantly on it, guided by no other sense, unless she could see through her eyelids.

Mr. Burnell then requested to know whether the inflammation attacking the caput cæcum coli in the cases now before the society, was referable to any indigestible matter lodged in the part, as he recollected cases, and one in particular, that died in St. Bartholomew's Hospital, where the mischief was found to arise from the detention of a considerable mass of mustard seed.

Dr. Johnson replied, that he had frequently observed it to be the case during the mania for taking that remedy, and that he had known fruits that must have been swallowed for some months retained; and that indigestible substances will remain in the cells of the colon for an unlimited time, keeping up immense irritation. In the cases that he had laid before the Society, he was not aware that these causes existed.

Dr. Webster, in corroboration of the last facts, briefly detailed a case (the minute particulars of which he could not recal to his recollection, having come under his notice some months back); the symptoms, however, he said, were vague, but they entirely subsided after the patient vomited up a bit of an eel that had remained in the stomach for six weeks unchanged.

Mr. Elwyn mentioned the case of a patient that had been received into the Middlesex Hospital, who, from an imbecile state of mind, was in the habit of swallowing raw carrots, cabbage stalks, and large pieces of orange peel: these produced considerable irritations, giving rise to loud hysterical screamings. He was treated by purgatives.

Several members at this stage of the discussion deprecated the use of strong purgatives, attributing intro-susceptions as arising entirely from their use, not duly taking into consideration the condition of the alimentary canal, so much so, that we began to be fearful that purgative medicines would be branded as little deserving of our notice.

A gentleman (whose name we were unacquainted with) argued, very rightly, that imaginations were very frequently produced through inanition.

Dr. Johnson, to prevent further misconception, either from what he might have offered himself, or what had fallen from different speakers, respecting purgatives, explained that indigestible substances set up an irritation at a certain spot of the alimentary canal, the tube contracts on that matter, and its circumference becomes smaller, and if active peristaltic action is induced, the contracted portion is forced down into a wider part below, and if drastic purgatives be administered in this condition, they cannot fail to aggravate the mischief.

Mr. Stretor considered that if a permanent pain existed in any portion of the intestinal tube, that he had found it far more advisable

to exhibit first two or three grains of calomel, followed by a free venesection, and then the aperient would be found to seldom fail to produce beneficial results.

At the adjournment, the President announced that there would be no meeting on the following Saturday evening, owing to Good Friday, it being customary to postpone attendance until the ensuing Saturday, which would be the last for this session. The amended laws of the Society were distributed to the members.

LONDON MEDICAL SOCIETY.

DR. WHITING in the Chair.

Ovarian Dropsy—Use of Iodine—Excision.

The subject of ovarian dropsy was resumed this evening, the discussion being chiefly directed to the employment of iodine in its treatment.

A case of ovarian disease was narrated by Mr. Kingdon, in which iodine was successfully employed, both internally and externally. From the immense size of the tumour, and its extent upwards, it was by many considered to be of hepatic origin, and, under that impression, the mercurial ointment was first employed, but unavailingly. The external application of iodine was then had recourse to, in the form of iodine, ℥j to an ounce of unguent. cetacei; the tincture was soon afterwards given in the dose of four drops three times a-day; a drachm of the ointment was rubbed in during the course of the four-and-twenty hours. Under this treatment the tumour gradually diminished, and a nucleus only was left; the general health also improving very materially.

Rather a curious fact was narrated in regard to this case; the patient had formerly suffered from hernia on the right side, which had not shown itself while the abdominal muscles were stretched by the enormous tumour which occupied the abdominal cavity, but as soon as this was diminished under the action of iodine, the rupture again appeared. Two other cases were alluded to in which benefit was derived from its use; but each patient, while under its influence, became the subject of inflammation of the womb. This was attributed by the narrator either to want of proper attention on the part of the patient, or to a peculiar predisposition to inflammation being induced by the administration of the iodine, and most especially in the diseased organs.

The experience of the Society appeared to be in favour of the use of iodine, even in the treatment of the disease under notice; it was unequivocally expressed in regard to its beneficial application in removing many other complaints. Cases were, however, mentioned where it proved injurious, and in some it seemed to cause a fatal termination. A case of enormous bronchocele was alluded to, in

which it reduced the swelling one third, but such severe irritative fever set in, that the patient sunk. Her medical attendant attributed the supervention of the fever to the iodine. It was also stated that Sir B. C. Brodie lost three patients during the past year from the injurious effects of iodine. A stranger to the Society remarked that the foreign physicians were exceedingly cautious in their employment of iodine, and seldom used it, except externally; he named Coindet, of Geneva (the original introducer into practice of this therapeutic agent), and Dr. Todd, of Rome. His statement, as far as regards Dr. Coindet, was at once contradicted by Dr. Johnson, who added, that he gave larger doses of the tincture than Mr. Kingdon, but that he considered an external application, consisting of iodine, hydriodate of potash, spermæti ointment, and the mercurial ointment, to be preferable. This he had found very beneficial, and he narrated a case of ascites, which he had successfully treated, in proof of his assertion. The patient, a merchant from Aberdeen, had been twice tapped, and was to have been operated on a third time, but on the day when it was to be done, he was so very weak, and the distension was so great, that it was feared he would die upon the table. He was therefore removed, and the ointment already alluded to prescribed. In the course of a short time great diuresis ensued, and the fluid contained in the abdomen was gradually absorbed; at the same time, an enlargement of the liver and spleen, which was present, subsided. The patient completely recovered, married, and had three children afterwards; the Doctor heard from him lately, and was informed that he enjoyed excellent health.

The question concerning extirpation of an ovarian tumour was resumed this evening in the course of the discussion, and we are bound in justice to say, that the opinion of the Society was expressed most forcibly, both against it, and also against the injection of the sac. The only argument that could be urged in favour of the former proceeding was, that occasionally the tumour has not any abnormal attachments, and may be readily turned out of the cavity of the abdomen; and it was argued that this condition might be ascertained to exist previous to excision, by the perfect rotation of the tumour; but, be it remembered, that in one of the operations at Edinburgh this condition of the enlarged ovary was supposed to exist, yet on laying open the abdomen the most extensive adhesions were found. It was mentioned, that of the six cases which occurred in the northern metropolis, and one which had been operated on in this, only one had survived, and even in that one the patient did not recover entirely, inasmuch as there were several tumours remaining in the abdomen, which were in all probability connected with the ovaries.

During the course of the evening, an intermediate discussion, or rather conversation,

took place between some of the members, on the subject of hepatic tumour, in the early part of the evening, and, later, on the comparative vitality of the ovarian cyst and peritoneal coat.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, April 14th, 1835.

HENRY EARLE, Esq. F. R. S., President, in the Chair.

This evening was read from the President a paper, entitled, "Some Observations on Fractures* of the Bones of the Pelvis," highly valuable and practical, evidently the result of no small attention to the important, but, it must be confessed, hitherto neglected subject. The author commenced by observing, that the greatest mischief to be dreaded from fractures of the bones of the pelvis, was the injury the important viscera contained within the cavity usually sustained; and these were generally caused by heavy weights passing over the pelvis, or falls received from considerable heights. The President was induced to offer to the Society the observations he had made on fractures of the bones of the pelvis, owing to writers not having treated of the symptoms by which he was enabled to arrive at a correct diagnosis, verified by post mortem appearances; death having occurred at distant periods from the receipt of the accidents, and not occasioned by the injury; or the symptoms had been confounded by writers with other fractures.

Two cases were detailed in confirmation.

CASE I.—A patient fell from a height of thirty feet, on his left side. The limb of the affected side was found not shortened, but was everted: pressure and rotating the leg caused uneasiness about the pelvis, and deep seated pain was felt in the hip joint, with injury of the urethra, as discoverable by the introduction of the catheter. The patient was discharged from the Hospital eight weeks after the receipt of the injury, and could walk almost as well as before the accident. Some time after, this patient fell under the care of Mr. Howship, and died of another affection. On examining the pelvis, three fractures were discovered; one through the ilium, a second of the pubis, and a third across the acetabulum in two directions—the outer surface of the ilium was considerably thickened with a deposition of ossific matter. The author was indebted to Mr. H. for the preparation (it was passed round to the members).

CASE II.—A robust-looking man, aged 44 years, was received into St. Bartholomew's Hospital in the month of August, 1834. On admission, stated he fell from a height of 16

* The Secretary included dislocations, but this, we suspect, originated from the habit he has acquired, from the terms fractures and dislocations frequently coming one after the other, as no allusion was made in the paper to them.
